and unlicensed spectrum (f2), respectively. That is, the carrier aggregation technique is not supported. However, since unlicensed spectrum cannot be used as the primary carrier component for signaling, licensed spectrum (f1) from LTE eNB is used for signal channel even when a device is located in the communication region of LTE-U AP. On the other hand, in scenario 2, the LTE eNB can transmit data through licensed spectrum (f1), while the LTE-U AP can use both licensed spectrum (f1) and unlicensed spectrum (f2), and then it can aggregate them by means of carrier aggregation to transmit data. Since LTE eNB and LTE-U AP use the same licensed spectrum (f1), devices in the cell boundaries experience a co-channel interference. Meanwhile, the LTE-U AP should employ an LBT mechanism regardless of the scenarios. Also, regardless of the context, the UE measures the radio signal strengths of the neighbor cells and the source eNB and reports the radio signal strengths to the source eNB or AP. Then, if the signal strength of the neighbor cell is stronger than that of the serving cell, the source eNB or AP triggers the handover procedure. The following features are observed through extensive simulations.

Handover in LTE-U/LAA,

Fig. 1 Evaluation scenarios (a) Scenario 1. (b) Scenario 2

The handover performance (i.e., TCP goodput) of LTE-U/LAA can be degraded due to the additional access delay that is defined as the time right after the handover to data transmission and the co-channel interference. Note that the additional access delay is caused by the LBT mechanism. That is, since the LTE-U AP conducts CCA to occupy unlicensed spectrum (i.e., LBT mechanism), more delay is caused when devices handover to LTE-U AP. Moreover, when the LTE-U AP uses both licensed spectrum and unlicensed spectrum (i.e., scenario 2), the co-channel interference between LTE eNB and LTE-U AP occurs. Then, licensed spectrum quality is degraded, and thus the handover performance can be degraded. Meanwhile, compared to the conventional LTE where handover can only be triggered by the mobility of the device, the handover in LTE-U/LAA can also be triggered due to the unavailability of unlicensed spectrum in the serving cell. Therefore, devices should spend more time searching available unlicensed spectrum even though the received signal strength from the serving cell remains strong, which can degrade the handover performance. From the above results, we can conclude that the handover scheme for LTE-U/LAA should be devised with the following design objectives:

- *To reduce the additional access delay*
- *To mitigate the influence of co-channel interference*
- *To avoid unavailability-triggered handovers*

Key Application

In LTE-U/LAA, an appropriate handover procedure should be developed with the consideration of the characteristic of the unlicensed channel to avoid the performance degradation (e.g., the additional access delay and co-channel interference).

Resource management for heterogeneous networks

Definitions

The performance of heterogeneous networks can be greatly enhanced through a reasonable multi-resources deployment scheme.

Historical Background

Since the rapid evolution of terminals continually explode the traffic demand in wireless communication systems, the network providers are facing an enormous challenge to enhance the system capacity. As improvements in spectral efficiency (SE) at link level approach its theoretical limits with existing techniques, heterogeneous network (HetNet) architecture has been proposed as a promising solution to improve SE per unit area (Navaratnarajah et al. 2013). A HetNet may consist of different sizes of cells with different radio access technologies (RATs), such as Third Generation Partnership Project Long-Term Evolution (3GPP-LTE), Worldwide Interoperability for Microwave Access (WiMax), and Wireless Local Area Network (WLAN).

Generally, resource management plays a key role in implementing efficient multiuser com-

munications over complicated wireless network environments. Owing to its potential performance improvement, there have been extensive research efforts on the resource management strategy for wireless HetNet (Liu et al. 2017; Gerasimenko et al. 2017). Apart from the capacity demand, considering energy efficiency (EE) is also of paramount importance for sustainable growth due to the increasing network usage of the latest advanced wireless communication devices (Chen et al. 2016). This section will indicate several possible research directions for the resource management in HetNets.

Business Diversity

Introduction

Video content traffic in the next-generation mobile cellular networks is estimated to exponentially grow, owing to the surge in requirements of bandwidth-intensive applications based on video streaming. To support the massive content delivery, caching and multicast are valuable to be exploited for the next-generation wireless networks (Poularakis et al. 2016). Note that recent advantages of *information-centric networking* (ICN) (Fang et al. 2015) instead of simply caching at base stations (BSs) can further facilitate the dissemination of information, since ICN is characterized by in-network caching that enables the network nodes to not only store but also name the contents passing through them, thus promoting the findability and delivery of the information. However, it is still worth noting that a video content is possibly demanded to be transcoded into several versions for adapting the complex network conditions and meeting the various device requirements. To promote computing capability of BSs, *mobile edge computing* (MEC) (Kumar et al. 2016) as a promising technique is necessary to be integrated at BSs for realizing video transcoding, since it is able to support agile and pervasive computation services through enabling cloud computing capability at BSs. Furthermore, a joint optimization of transcoding, caching, and multicast is crucial, since the process value and

the result value of both caching and computing depend on communications.

Wireless network virtualization has also attracted great attentions, since it is able to significantly reduce the capital expenses and the operational expenses of wireless access networks as well as core networks (Liang and Yu 2015). Through virtualization, wireless network infrastructure can be decoupled from their provided services, and various users with differentiated services requirements can dynamically share the same infrastructure, thereby maximizing the system utilization.

Wireless network virtualization provides a better platform to install ICN and MEC functions in HetNets. With an effective resource management strategy, the diversity demands of user services can be better satisfied over the virtualized HetNets networks based on ICN and MEC. Therefore, this subsection focuses on the combination of ICN and MEC in virtualization and the efficient allocation of the limited resources including the computing, caching, and communication resources.

A Feasible Multi-resources Deployment Plan

Figure 1 illustrates the proposed HetNets virtualization framework for transcoding, caching, and multicast. The virtualization procedure can convert such a physical HetNets with abundant physical resources to several virtual networks. Compared to the traditional networks, where the whole system is designed to support different kinds of services, the virtualized HetNets can focus on only one type of service and bring in a better user experience. As shown in Fig. 1, two virtual networks are created according to the quality-of-service (QoS) requirements of multicast groups and the properties of contents. The personal services, such as text, and the real-time services, such as voice call and video meeting, can be executed in virtual traditional HetNets without caching and computing functions, i.e., virtual network 2, since the contents of this kind of services are private and of low reuse probability. The virtual ICN-/MEC-enabled HetNets, i.e., virtual network 1, are more specified on video streaming services. Assume that the video

contents required by different multicast groups are encoded into several versions with different bitrates to adapt the complex network conditions and to meet the various device requirements. With the help of ICN, the video content versions with higher popularity can be cached at BSs for alleviating the backhaul usage. With the help of MEC, some of the video versions are not necessary to be cached and can be directly transcoded from the already cached versions.

In this way, there are two issues to be solved at each BS: (i) For a content, which versions are valuable to be stored? (ii) Which versions are chosen to be computed (transcoded)? The solutions of these two questions result in two kinds of alternative costs: caching cost and computing cost. Note that these two kinds of costs are competing with each other. If a BS has a larger storage capacity, the more video versions can be cached, so that the probability of computing will be reduced, the result of which leads to a lower computing cost. In contrast, if a BS is assigned more computing resource, the less video versions need to be cached, so that the storage space can be saved, the result of which leads to a lower caching cost. In conclusion, the resource management strategy should have the ability to jointly optimize the utilities of caching, computing, and communications, through selecting the appropriate virtual network for each mobile user and storing the proper versions at each BS.

Communication Reliability

Introduction

WLAN/femtocell interworking system, as a typical example of HetNets, has been recognized as a promising technique to cater for the ever-increasing service demand (Gamage et al. 2014). Since the complicated network environment is always with the high operation overhead, self-organizing network (SON) has been proposed to realize the automated network management and the low operation cost (Barco et al. 2012). As one of the main functions of SON, self-healing is capable of detecting, diagnosing, and compensating the abrupt network failure.

Heterogeneous Networks Through Multi-resources Deployment, Performance Enhancement for, Fig. 1
Illustration of HetNets virtualization framework with ICN and MEC

Note that in a real scenario, the same region is usually covered by a number of networks with different sizes and RATs. While implementing the self-healing functions for such a real scenario, not only the parameters but also the methods have to be designed to apply to each specific network (Zhou et al. 2017). Therefore, it is quite tricky but worthy of designing a resource management strategy for self-healing, which can be well applied in such a complicated scenario.

A Reliable Resources Deployment Plan

The key challenge for self-healing in WLAN/femtocell system is the high complexity caused by existence of multiple medium access control layer (MAC) and physical layer (PHY) techniques. It should be noticed that the feasible transmission rate of the interworking system depends on MAC and PHY techniques of the different networks (Gamage et al. 2014). Therefore, to enable self-healing for the interworking system, the proposed resource management scheme is designed based on MAC of IEEE

802.11 WLANs and PHY of femtocells. WLANs and femtocells are connected to a centralized unit viewed as operation and management (OAM). Assume that faulty networks have already been detected by any outage detection method, and the users in faulty networks, named as compensation users, can be continually served by neighbor normal WLANs or femtocells with the help of OAM.

WLANs usually adopt the distributed coordination function (DCF) mechanism with request-to-send (RTS)/clear-to-send (CTS) handshaking. Figure 2 illustrates the DCF mechanism with the downlink compensation access. In the traditional DCF-based WLAN system, carrier sense multiple access with collision avoidance (CSMA/CA) protocol can effectively avoid the collision of data frames. However, this kind of protocol cannot guarantee the required utilization of the downlink transmission, especially when a large number of users access the WLAN. Thus, a required utilization ratio ψ is introduced and defined as the ratio of the downlink throughput to the uplink

Heterogeneous Networks Through Multi-resources Deployment, Performance Enhancement for, Fig. 2
DCF mechanism with downlink compensation access

throughput, to ensure an adequate level of the fairness between the downlink and the uplink. If the current utilization ratio is less than ψ , AP can preferentially transmit data frames without collision after point interframe space (PIFS), since PIFS is shorter than DCF interframe space (DIFS). In this way, while implementing self-healing for WLANs, the downlink utilization can be well guaranteed, for the users within the normal networks and fault networks.

For the femtocells, a joint subcarrier and power allocation scheme is usually adopted for performance optimization. However, many existing works are based on the assumption that channel gain from transmitter to receiver is perfectly estimated. In practice, it is really difficult and expensive to accurately estimate instantaneous channel between transmitter and receiver, because of channel fluctuations, limited feedback capacity, and channel estimation and quantization errors (Fang et al. 2017; Chang et al. 2017). Inaccurate channel estimation results in imperfect channel state information (CSI), which leads to the collision of users and the outage of networks. Therefore, the resources need to be managed for satisfying the acceptable outage probabilities and restricting the collision probabilities for each user.

The optimization problem for self-healing can be designed to jointly optimize the allocations of users, subcarriers, and power, which is a nonconvex mixed-integer nonlinear problem (MINLP). To solve the MINLP suboptimally but effectively, the compensation users can be allocated

to normal WLANs firstly, since the co-channel interference issue needs to be addressed in the resource optimization of femtocells. If the users in WLANs tend to be saturated, the remaining compensation users will be allocated to normal femtocells, and then the joint subcarrier and power allocation scheme can be executed for performance optimization.

Key Applications

A reasonable multi-resources deployment strategy is able to promote the network performance. In addition, the business diversity and the communication reliability are two major issues that could be solved through reasonable multi-resources deployment. Therefore, the resources deployment plays a key role in implementing efficient multiuser interactions over different wireless networks, such as cellular network, femtocell, WLAN, and other environments.

Introduction

In recent years, the use of mobile data has grown by 70% to 200% annually. What is more worrying is that the bursty nature of wireless data traffic makes traditional network capacity planning obsolete (Zhang et al. 2018). Almost all operators and suppliers believe that small cells (such as picocells, femtocells, and relay nodes) are a promising solution to improve local capacity in traffic hotspots, thereby relieving macrocell burden. In order to effectively divert macrocell traffic to small cells, researchers have done a lot of research, mainly in indoor situations (Hwang et al. 2013).

Licensed spectrum is scarce in cellular networks. However, deploying small cells within the coverage of macrocells also hopes to obtain the same spectrum as macrocells (Chu et al. 2013). A frequency reuse factor of 1 in 3G HSPA+ and 4G LTE/LTE-A systems has proven to yield high gains in network capacity. If there is no rich extra spectrum for mobile communications, future cel-

lular networks will have to actively explore new and more efficient methods of frequency reuse. Therefore, it is highly probable that the ultra-intensively deployed small cell may be affected by interference between the small cell and macro-cell co-channel and adjacent small cells.

According to the current situation, both industry and academia are actively studying all possible spectrum resources, including unlicensed frequency bands, to provide more timely and quality services (Huawei 2013). Industry believes that the unlicensed 2.4 GHz and 5 GHz bands in Wi-Fi systems are important candidates for providing additional frequency bands for mobile communications. An unlicensed band originally targeted at 5 GHz may have up to 500 MHz of spectrum available.

At present, the vast majority of mobile devices, such as mobile phones and tablets, support Wi-Fi access, and more Wi-Fi access points will be available in the future (Zhang et al. 2015). Especially in developed cities, the density of Wi-Fi access points has reached more than 1,000 per square kilometer. Such a widely deployed Wi-Fi system plays a decisive role in the data traffic diversion of the cellular network and is more prominent in indoor traffic hotspots and poor signal areas. As the FCC decided to use 100 MHz of spectrum in the 5 GHz band for Wi-Fi use, operators have more opportunities to expand data services to Wi-Fi systems. Wi-Fi access points have even been regarded as a distinct tier of small cells in heterogeneous cellular networks. At present, the industry is exploring the use of unlicensed spectrum of LTE/LTE-A under the Wi-Fi system. The coexistence and interworking of Wi-Fi and heterogeneous cellular networks will become a research hotspot and research trend in the future. If the interference between Wi-Fi and cellular networks can be effectively mitigated, the joint deployment of Wi-Fi and cellular networks under unlicensed spectrum will significantly increase the overall system capacity of heterogeneous networks.

Because of the huge benefits of joint deployment of Wi-Fi and cellular networks under unlicensed spectrum, more and more research groups are starting to join. In Hajmohammad

and Elbiaze (2013), the authors proposed a quality of service (QoS)-based strategy to split the unlicensed spectrum between Wi-Fi and femtocell networks. Although the unlicensed spectrum splitting scheme considers fairness between Wi-Fi access points and femtocells, the split use of the spectrum between two systems prohibits a high crossnetwork throughput. In Charitos and Kalivas (2013), the authors discussed the deployment of a heterogeneous vehicular wireless network consisting of IEEE 802.11b/g/e Wi-Fi and IEEE 802.16e WiMAX systems inside a tunnel for surveillance applications and specifically evaluated the handover performance of the hybrid Wi-Fi/WiMAX vehicular network in an emergency situation. In Almeida et al. (2013), time-domain resource partitioning based on the use of almost blank subframes (ABSs) was proposed for LTE networks to share the unlicensed spectrum with Wi-Fi systems. Qualcomm has recently proposed to deploy LTE-A in the unlicensed 5 GHz band currently used mostly by Wi-Fi. The main idea is to deploy LTE-A as supplemental downlink (SDL) in the 5725–5850 MHz band in the USA, with the primary cell always operating in the licensed band. Verizon and Ericsson are also exploring similar ideas. Huawei and CMCC have investigated the availability, commonality, and feasibility of integrating the unlicensed spectrum to International Mobile Telecommunications-Advanced (IMT-A) cellular networks (Huawei 2013). On pre-commercial multicell networks, LAA-LTE achieves better coverage and capacity in the 5 GHz unlicensed spectrum than Wi-Fi alone have been proved. So there are worries that LTE-U will occupy all the bandwidth of Wi-Fi in ultradense deployment.

There are still many technical problems with the coexistence of Wi-Fi, and cellular networks under unlicensed spectrum, such as efficient spectrum sharing (Zhang et al. 2014) and interference mitigation (Zhang et al. 2016), have not been sufficiently addressed. In Dimatteo et al. (2011), the authors proposed an integrated architecture exploiting the opportunistic networking paradigm to migrate data traffic from cellular networks to metropolitan Wi-Fi access

points. Bennis et al. (2013) introduced the basic building blocks of cross-system learning and provided preliminary performance evaluation in an LTE simulator overlaid with Wi-Fi hotspots. For the unlicensed spectrum sharing deployment of Wi-Fi and LTE-A systems, the co-channel interference between Wi-Fi tier and LTE-A tier can be mitigated by using ABSs, in which the interfering tier is not allowed to transmit data, and the victim tier can thus get a chance to schedule transmissions in the ABSs with reduced cross-tier interference (Liang et al. 2012). Moreover, it has been demonstrated that by estimating the number of co-channel transmitters and knowing the deployment density of network nodes in a region, the average channel quality at any point in a coverage area can be inferred (Wang et al. 2014).

In this entry, we propose a system architecture that supports coexistence of Wi-Fi and heterogeneous cellular networks to share unlicensed spectrum. Based on the system architecture, we first provide an in-depth review of the ABS scheme used for mitigating the co-channel interference from small cells to Wi-Fi systems and propose a spectrum-sensing-based fair ABS scheme without priority. We then present an interference avoidance scheme based on small cells estimating the density of nearby Wi-Fi transmissions to facilitate the unlicensed spectrum sharing between small cells and Wi-Fi access points. Simulation results are provided to evaluate the performance of the proposed system architecture and interference avoidance scheme in facilitating coexistence of Wi-Fi and 4G heterogeneous cellular networks in unlicensed spectrum.

Network Architecture for Wi-Fi and Cellular Coexistence

In this part, we research the system architecture where several Wi-Fi access points and small cells coexist in the coverage area of a macrocell.

Heterogeneous Network Architecture

As shown in Fig. 1, multiple Wi-Fi access points and small cells coexist in a macrocell coverage area in the system structure. The macrocell, small

cells, and Wi-Fi access points share the same unlicensed spectrum for providing radio access to users, millimeter-wave radio is used for small cell backhaul links, and device-to-device (D2D) communications are supported based on Wi-Fi Direct or LTE Direct. As shown in Fig. 1, the control plane (C-plane) and user plane (U-plane) are split on the radio links associated with small cells. Specifically, the C-plane of user equipments (UEs) associated with a small cell is provided by the macro eNB in a low-frequency band, while the U-plane of UEs associated with a small cell is provided by their serving small cell in a high-frequency band. For UEs associated with the macrocell, both the C-plane and U-plane of their radio links are provided by the serving macrocell. Since the C-plane of small cell UEs is managed by the macrocell, the radio resource control (RRC) signalings of small cell UEs are transmitted from the macrocell, and the handover signaling overhead between small cells and the macrocell can be much reduced (Nakamura et al. 2013). Regarding Wi-Fi access points as a type of small cells, the C-plane and U-plane split can be applied in a Wi-Fi/macrocell scenario, where the C-plane of UEs associated with a Wi-Fi access point is provided by the macro eNB in a low-licensed-frequency band, while the U-plane of UEs associated with a Wi-Fi access point is provided by their serving Wi-Fi access point in a high-unlicensed-frequency band. The interworking of Wi-Fi and cellular networks benefits from the split of C-plane and U-plane in terms of mobility robustness, service continuity, reduction in cell-planning efforts, energy efficiency, etc.

In an ultra-intensively deployed small cell, expensive wired backhaul is not feasible when considering the small cell backhaul problem. In the meanwhile, in-band wireless backhaul solutions using the licensed spectrum may not be feasible either, because of the scarcity of the licensed spectrum (Sooyoung et al. 2013). Recently, the millimeter-wave bands, such as the unlicensed 60 GHz band and the low interference licensed 70 GHz and 80 GHz bands, have been considered as promising candidates for the small cell backhaul solution (Zhang et al. 2017a). This is motivated by the huge frequency bandwidth (globally har-

Heterogeneous Small Cell Networks, Fig. 1 Network architecture of LTE-A and Wi-Fi coexistence

monized over more than 6 GHz millimeter-wave spectrum) that can be exploited and the spatial isolation supported by highly directional beams. At the same time, the new IEEE 802.11ad standard, a.k.a. WiGig, uses the unlicensed 60 GHz millimeter-wave band to deliver data rates of up to 7 Gbps. This adds a large amount of new frequency bandwidth to existing Wi-Fi products, such as 802.11n operating in the 2.4 GHz and 5 GHz bands and 802.11ac operating in the 5 GHz band.

For providing radio access, the macrocell, small cells, and Wi-Fi access points partake the unlicensed spectrum. The network architecture in Fig. 1 integrates the coexistence of Wi-Fi and cellular networks and facilitates smart management of data traffic in mobile operators' networks. For instance, the data traffic could be dynamically routed to the optimal radio interface for a particular application and user, with network congestion, reliability, security, and connectivity cost taken into account. As can be seen from Fig. 1, the primary carrier always uses licensed spectrum to transmit control signaling, user data, and mobility signaling, while

the secondary carrier(s) use unlicensed spectrum to transmit best-effort user data in the downlink and potentially the uplink.

Handover Procedure Between Wi-Fi and LTE/LTE-A

One of the key aspects of interworking between Wi-Fi and LTE/LTE-A systems is seamless mobility. In order to ensure the user's QoS during the handover, there should be no packet loss or radio link failure. Current Wi-Fi systems do not support interworking between Wi-Fi and LTE/LTE-A systems, but this is necessary because users often move between Wi-Fi access points and cellular network coverage areas. In 3GPP Rel-11, trusted WLAN gain, the Enhanced Packet Core (EPC) is built on S2a-based Mobility over GPRS Tunnelling Protocol (SaMOG), which is enhanced in 3GPP Rel-12 to provide traffic steering and mobility between LTE-A and Wi-Fi networks and to optimize the use of network resources. The seamless and non-seamless handover solution between 3GPP and non-3GPP access networks is the 3GPP standard

Heterogeneous Small Cell Networks, Fig. 2 Handover procedure between Wi-Fi and LTE/LTE-A

TS 23.401. The role of these standards is to enable users to continue using data services while passing through macrocells, small cells, and Wi-Fi hotspots. In the network architecture shown in Fig. 1, a UE can switch between Wi-Fi and cellular networks through the core network (CN) gateway (GW). In Fig. 2, the CN GW-based handover procedure between a source Wi-Fi (macrocell) and a target macrocell (Wi-Fi) is given. Since the C-plane of the Wi-Fi user equipment is managed by the macrocell, the RRC signaling of the Wi-Fi user equipment is sent by the macrocell, so that the signaling overhead between the Wi-Fi access point and the macrocell can be greatly reduced (Zhang et al. 2015).

Almost Blank Subframe Allocation

This section discusses almost blank subframe (ABS) schemes and does not have priority to mitigate the co-channel interference of small cells with Wi-Fi systems.

Coexistence Without Priority

In recent times, regulators are considering the possibility of coexisting multiple different radio access technologies (RATs) in the same frequency band. These include licensed bands (e.g., television spectrum) and unlicensed bands (e.g., amateur spectrum). At present, the USA, Canada, and the UK are the main countries, and supervision is under way to allow the operation of space equipment (WSDs), for example, the IEEE 802.22 fixed point-to-point cognitive radio transmissions in television white space and more lately the IEEE 802.16h wireless broadband protocols.

The secondary user uses spectrum sensing technology in the licensed band to prevent interference with the primary user because the primary user and the secondary user have a clear concept. This can be obtained by identifying the primary transmission using spectrum sensing or geo-location database operations. However, there is currently a lack of research activities to investigate how auxiliary users associated with different

RATs prevent or mitigate co-channel interference between each other. In an unlicensed band with no primary user and no secondary user concept, there are similar challenges between different RATs sharing the same spectrum.

In this chapter, we relate to the coexistence of two RATs without priority ranking as *coexistence without priority*. More specifically, in order to solve the problem of inconsistency between the primary user and the secondary user, we have focused on allowing cellular communications to coexist with Wi-Fi communications on an equal footing. The new content here refers to the coexistence of two different RATs and the impact on the interference graph when these two RATs do not coexist. Although the coexistence of contention-based systems has been explored (e.g., 802.11 and 802.15 systems) (Yuan et al. 2010), the absence of prioritization between non-competitive systems (LTE) and contention systems (Wi-Fi) is a bad exploration for competing systems. In fact, we can think that it is entirely reasonable to suspect that LTE's allocation-based transport protocol may completely prevent the conflict-based Wi-Fi protocol. In addition, the density of small cells is getting higher and higher, and this interpretable defect in the same frequency band may cause serious capacity problems.

The communication protocol in the coexistence of multiple RATs can operate in its default normal mode or coexistence mode. The latter is triggered when proximity detects another RAT and requires action. Coexistence mechanisms can be divided into two groups: (i) those that require message exchanges between nodes or RATs and (ii) those that are not needed. In general, cross-RAT coordination is very difficult because of different protocol development processes and vendor differences. Therefore, in the next section, we will review the non-collaborative coexistence mechanism that allows LTE to coexist with Wi-Fi in the unlicensed spectrum.

Random Almost Blank Subframe Allocation

In Almeida et al. (2013), autonomous (uncoordinated) coexistence between LTE and Wi-Fi

was achieved through LTE transmission of ABSs under a 3GPP Rel-10 time division duplex (TDD) scheme. ABS is a subframe of power or content reduction. Because several synchronization channels (e.g., common reference signals) are reserved, they are backward compatible with 3GPP Rel-8 and Rel-9. The ABS is triggered by the coordination message between the eNodeBs through the X2 interface to avoid interference between the cells of the same RAT. The frequency of ABS transmission can adapt to the time-varying interference environment. For the foregoing reasons, in order to avoid interference between cells of different RATs, coordinated messaging between cells of different RATs is a challenging task. Therefore, ABS is sent randomly at a certain speed, does not require coordination, and does not require backward compatibility with previous releases of undistributed bands (Almeida et al. 2013). The core idea of this idea is that in a randomly acquired ABS, the Wi-Fi access point can detect that the channel is idle and transmit after its contention-based protocol. Based on this, the allocation properties of LTE transmissions can be suppressed in a way that avoids coordination or spectrum sensing, but this comes at the price of reduced LTE spectrum efficiency and network capacity.

In Fig. 3, the maximum achievable throughput for an LTE or Wi-Fi (802.11n) cell under different normalized traffic loads is plotted, with LTE operating either under the original mode or with 30% of the subframes randomly selected as ABSs. The parameters used in the simulation can be found in Table 1. The results show that in the original mode, the LTE cell capacity is saturated at about 84 Mbps and the Wi-Fi cell capacity is saturated at 64 Mbps. The reason for this difference is due to the use of a discrete modulation and coding scheme (64QAM turbo code). As the LTE traffic load increases, the capacity of all cells decreases due to increased radio resource usage and the resulting increased interference. The LTE cell capacity attenuation is slower than the Wi-Fi capacity. The *superlinear* degradation of Wi-Fi capacity may finally lead to 0 Mbps. By employing 30% ABSs in LTE, the Wi-Fi capacity is improved significantly at high

(normalized to cell capacity), with LTE operating with (a) original mode and (b) ABS

Heterogeneous Small Cell Networks, Table 1 Simulation Parameters

Parameter	Value
LTE carrier frequency	2100 MHz
Wi-Fi carrier frequency	2400 MHz
LTE cell density	3 per km ²
Wi-Fi density	300 per km ²
LTE cell transmit power	40 W
Wi-Fi transmit power	1 W
Pathloss	3GPP urban micro
Peak LTE throughput	84 Mbits/s (64 QAM SISO)
Peak 802.11n throughput	65 Mbits/s (64 QAM SISO)

ness among networks, but ABS mechanism will decrease the capacity of LTE and Wi-Fi networks.

Interference Avoidance with Neighborhood Wi-Fi Density Estimation

This part researches an interference avoidance scheme based on small cells estimating the density of nearby Wi-Fi access points to facilitate their coexistence while sharing the same unlicensed spectrum.

LTE traffic loads, while the LTE cell capacity falls by 10–24 Mbps. It should be noted here that, with LTE ABS transmission, the capacity reduction of LTE and Wi-Fi will be slowed down because the random ABS can reduce cross-layer and interlayer intercell interference. It is worth noting that the overall total capacity of LTE and Wi-Fi is actually reduced by ABS, which indicates that the random ABS mechanism is more conducive to fairness than to the overall capacity.

In conclusion, LTE transmitters can randomly transmit ABSs when LTE and Wi-Fi share same spectrum and ABS mechanism can benefit fair-

Inference Framework

It can be seen that avoiding co-channel interference in a network with a high interference intensity can enhance the long-term system capacity (Liang et al. 2012; Zhang et al. 2017b). However, coordinating interference avoidance on the radio resource management (RRM) level needs a large volume of coordination information from multiple base stations (BSs) through the X2 interface. Especially, every BS requires to know whether its adjacent BSs are transmitting on each available radio resource block. This level of coordination taxes the *backhaul capacity*, while any *delay* in

information sharing may cause the interference avoidance performance to falter.

In Wang et al. (2014), an interference estimation technique that does not require information sharing between BSs and UEs was designed based on BSs sensing the spectrum and estimating the number of co-channel transmissions in a defined observation region. By estimating the number of co-channel transmitters and receiving the information about cell density in the district, the average channel quality at *any random point* in a coverage area can be inferred. As the expressions are tractable, the computational complexity is very low. This methodology can be applied to a K-tier heterogeneous network by leveraging a stochastic geometry framework and an opportunistic interference reduction scheme, which was shown to approach the interference estimation accuracy achievable by information exchange on the X2 interface (Wang et al. 2014).

The inference framework is based on the assumption that all cells have spectrum sensing equipment (low-cost spectrum sensing equipment for 2–5 GHz is now readily available). On each frequency band f , each sensor in cell (located at distance h from the BS) is capable to detect the power density P_f from all co-channel transmitters in an unbounded zone. Based on the spatial distribution of co-channel cell deployments (Haenggi 2005), the density of co-channel transmissions λ_f can be inferred from the P_f measurements (Wang et al. 2014):

$$\lambda_f \propto \frac{\sqrt{P_f/P}}{Q(h, \alpha)} \quad (1)$$

where α is the pathloss distance exponent, P is the average transmit power of the BSs, and the function $Q(h, \alpha)$ is given in Wang et al. (2014). This inference framework can be applied to a K-tier heterogeneous network which consists of macrocells, femtocells, and Wi-Fi access points. Figure 4 shows a femtocell sensing the received power spectrum to infer the number of co-channel transmitters in a three-tier heterogeneous network. For example, the estimated transmitter activities on the considered frequency band are 50% of LTE macrocells, 100% of LTE

femtocells, and 25% of Wi-Fi access points. This spectrum sensing mechanism is not capable to know which cells are transmitting, but it provides a statistical notion for a BS to infer the channel quality of a served user.

Based on the inferred density of co-channel transmissions λ_f in the vicinage, the signal-to-interference ratio (SIR) on frequency band f at distance d away from the sensing BS is estimated as:

$$\text{SIR}_{f,d} \propto P_f^{-1} \left[\frac{Q(h, \alpha)}{Q(d, \alpha)} \right]^2, \quad (2)$$

where the constant of proportionality is the received signal strength.

Simulation Results

Figure 5 shows the simulation results of peak cell throughput versus normalized cell traffic load for a variety of static and dynamic interference mitigation schemes (Wang et al. 2014; Turyagyenda et al. 2012). The baseline is a hard frequency reuse 1 (HFR1) scheme, which shows a peak velocity of 58 Mbps/cell when the cells are unloaded (i.e., minimum intercell interference). This value will fall to 40 Mbps/cell for fully loaded cells without interference mitigation (i.e., maximum intercell interference). A similar trend exists for HFR3. The soft frequency reuse with a power back-off factor of 0.5 (SFR P0.5) performs better than the previous two schemes. We can see from Fig. 5 that the TDD-based sequential game coordinated (SGC) interference avoidance scheme achieves a much higher peak cell capacity than the HFR and SFR schemes at low and medium cell traffic loads. The uncoordinated interference avoidance scheme proposed in Wang et al. (2014) provides the highest peak cell velocity at high traffic loads and achieves over 90% the peak cell capacity of the SGC interference avoidance scheme which requires channel state information.

Discussion and Challenges

The disadvantage with a TDD-based coordinated interference avoidance scheme is the need for two prerequisites (Turyagyenda et al. 2012): (1) cell

Heterogeneous Small Cell Networks, Fig. 4 Illustration of a femtocell inferring the number of co-channel transmitters from a three-tier cellular and Wi-Fi heterogeneous network by sensing the received power spectrum (Wang et al. 2014)

Heterogeneous Small Cell Networks, Fig. 5 Plot of peak cell capacity versus different normalized cell traffic loads for a variety of static and dynamic interference mitigation schemes (Wang et al. 2014; Turyagyenda et al. 2012)

pairing or clustering and (2) static or dynamic assignment of cell priority. Effective cell pairing often involves the association of cells that are dominant interferers to each other. However, this may not always be the case. For example, the antenna boresight of BS A is pointing at BS B,

but the antenna boresight of BS B is pointing at a direction away from BS A . Alternatively, two cells that are closest to each other will be paired together. Cell priority assignment refers to the process of assigning different transmission priorities to cells. Random access, traffic-weighted, and QoS-weighted cell priority assignments have been considered in the literature.

Conclusion

In this entry, we have investigated the potentials and challenges associated with coexisting Wi-Fi systems and heterogeneous cellular networks sharing the unlicensed spectrum. We have introduced the network architecture for LTE/LTE-A small cells to explore the unlicensed spectrum used by Wi-Fi systems. The ABS mechanism and an interference avoidance scheme have been proposed to mitigate the interference between Wi-Fi and LTE/LTE-A systems when both transmitting in the same unlicensed spectrum. Simulation results have shown that with the proper use of ABS mechanism and interference avoidance schemes, heterogeneous and small cell networks can improve their capacity by using the unlicensed spectrum used by Wi-Fi systems without affecting the performance of Wi-Fi.

Hidden and Exposed Terminal Problems

Zijun Gong and Fan Jiang

Synonyms

[Exposed node problem](#); [Hidden node problem](#)

Definition

The hidden node problem refers to the situation where two nodes try to send packets to a third node simultaneously because they don't know the existence of each other. The exposed node problem refers to the situation where a node refrains from transmitting because a neighbor node is sending packets.

Historical Background

The well-known hidden terminal and exposed terminal problems severely reduce network throughput in wireless ad hoc networks, as shown in Fig. 1.

The hidden terminal problem is illustrated in subfigure (a). As we can see, node A can hear node B and node C, while node B and node C cannot hear each other. Assume node B is sending data to node A and node C also has data to send. In this case, node C doesn't know that node B is transmitting and will start data transmission to node A. As a result, packets from node B and C will collide at node A. The exposed terminal problem is depicted in subfigure (b). Node A and B are deployed in Area I, while node C and D are deployed in Area II. Assume A can hear B and C can hear D. Signal from A cannot be heard by C, but can be detected by D. In this case, when A is sending packets to B, D can safely send packets to C at the same time without collision. However, D will refrain from doing this, because D mistakenly thinks that the channel is occupied.

As we can see, both the hidden terminal problem and the exposed node problem will reduce network throughput for different reasons. For the hidden terminal problem, performance loss is caused by the retransmissions after collisions. On the other hand, the exposed terminal problem is not efficient because some communications that can be conducted simultaneously are blocked. Many different protocols have been proposed to overcome these two issues. The basic idea is to add a control channel, on which communi-

Hidden and Exposed Terminal Problems,

Fig. 1 The hidden terminal and exposed terminal problems

cations among different nodes can be coordinated. Here, we will briefly review some of these protocols.

The busy tone multiple access (BTMA) protocol was proposed in 1975 to tackle these issues (Tobagi and Kleinrock 1975). In BTMA, the channel between transmitter and receiver is divided into a data channel and a control channel. These two channels lie on different frequencies. When a transmitter wants to send packets to a receiver, it will first sense the control channel. If a busy tone is sensed, the transmitter will back off randomly and transmit the packets later. On the other, it will start transmission and put a busy tone on the control channel simultaneously. When the receiver senses the data on its data channel, it will also put a busy tone on its control channel. This protocol successfully reduced collision probability. However, the bandwidth utilization is very low.

The MACA (Multiple Access with Collision Avoidance) scheme is another scheme (Karn 1990). Before sending packets, the sender will send a *request to send* (RTS) message to the corresponding receiver. If the receiver is currently ready to receive data, it will reply a *clear to send* (CTS) message. Then, the sender can safely send data to its intended receiver. Reference (Bharghavan et al. 1994) presented a variant of MACA.

To improve bandwidth utilization, the dual busy tone multiple access (DBTMA) protocol was proposed in Deng and Haas (1998). Similar to BTMA, it has both data and control channels. However, there are four types of signals on the control channel: the request to send packet, the

clear to send packet, the busy tone for transmitting (BTT), and the busy tone for receiving (BTR). Whenever a node wants to transmit packets, it will first sense the control channel. If there is a BTR, it means that a neighbor node is receiving packets, and the transmitter needs to wait. Otherwise, the transmitter will send a RTS packet. Upon receiving the RTS packet, the receiver will first sense the control channel. If BTT is detected, it means that a neighbor node is transmitting, and the receiver cannot receive packets at this moment. On the other hand, the receiver will send the transmitter a CTS packet and put a BTR on control channel. Upon receiving the CTS packet, the transmitter will put a BTT on control channel and start transmission. After all the packets are transmitted, both sides will turn off the busy tones. Compared with the other RTS/CTS-based protocols, the DBTMA shows better network utilization.

Another variant of BTMA is the receiver-initiated tone multiple access protocol (RI-BTMA) (Wu and Li 1987). In this protocol, both control channel and data channel are divided into slots of the same length. When a node wants to transmit something, it first senses the control channel. If busy tone is detected, it will wait for the next free slot. Then, a preamble is transmitted on data channel, which contains the identification of the intended destination node. Upon receiving the preamble, the destination node will put a busy tone on the control channel, until all packets have been successfully received. After transmission, both receiver and transmitter will cancel the busy tone. On the other hand, if the preamble is not successfully received by the intended receiver,

the sender will not receive acknowledgment from the receiver. In this case, the sender will wait for the next free slot until communication is built up. The RI-BTMA protocols can be divided into two types: the basic one and the controlled one. For the basic type, nodes cannot buffer data on collisions. As a result, collided packets cannot be retransmitted. Besides, when network load is intense, this protocol is not stable, because nodes do not have queuing system for incoming packets. To solve these problems, the controlled protocol is proposed. Nodes can buffer the failed packets and retransmit them. Once the buffers are not empty, the node will work in backlogged mode. In this case, the node will first retransmit the failed packets and buffer the incoming packets.

Foundations

This part focus on analyzing how the reviewed protocols overcome the hidden and exposed terminal issues. Besides their advantages and limitations will also be discussed. Moreover, we will briefly introduce the IEEE 802.11 RTS/CTS mechanism.

Adopting the example in Fig. 1, for BTMA, when node B is sending packets to node A, node A will put a busy tone on the control channel. When node C also wants to send packets to node A, it will first sense the control channel. Due to the busy tone, node C immediately understands that node A is receiving packets from some other node. Therefore, it will wait until the busy tone is cancelled. As a result, the hidden node issue is resolved. For the exposed node issue, when node A is transmitting packets to node B, node B will put a busy tone on control channel. When node D wants to send packet node C, it will first sense the control channel. Because node B is out of the communication range of node D, the busy tone cannot be heard by node D. Therefore, although node D hears node A is transmitting, it knows that the receiver is not in its range. Node D can safely and confidently start its transmission to node C. This protocol has very low complexity and can be easily implemented. However, it cannot be used

in highly populated networks because of its low efficiency.

The MACA protocol works in a different way. Still adopting the example in Fig. 1, when node B is transmitting to node A, node A puts a busy tone on control channel. Therefore, node C knows that A is receiving packets from other nodes, which means the hidden terminal problem is solved. On the other hand, when node A is transmitting to node B, B will put a busy tone on control channel. Node D overhears node A, but it cannot hear the busy tone from node B. As a result, node D realizes that the receiver (node B) is not in its communication range, and it is safe to start the transmission to node C.

The IEEE 802.11 RTS/CTS mechanism is a variant of the MACA protocol. In this mechanism, when a node wants to transmit packets to a destination node, it will first send RTS. When the destination node replies with CTS, the sender will transmit a short Data-Sending packet, which contains the information about the length of the data packet to be transmitted. After this, the data packet can be transmitted, and the receiver will reply with ACK. It should be noted that the sender can only transmit one packet in every round for fairness. After every transmission, the sender waits for a random time and competes for medium access with other nodes. If a node overhears RTS, it means some neighbor node is waiting for the CTS message. Therefore, this node needs to wait until it overhears CTS or for a certain time so as to guarantee the un-interfered reception of the CTS of the neighbor node. On the other hand, if a node overhears CTS, it means that some neighbor node is trying to receive data. Therefore, this node needs to wait until the transmission is over, as indicated by ACK. If a node is in the vicinity of the sender but not the receiver, it can hear the RTS and DS, which indicate the successful exchange of RTS/CTS. Therefore, it needs to wait for the estimated transmission time plus a random back off.

This protocol is not fair in some scenarios. For example, when the receiver is in the communication range of an active node receiving packets from another node, the incoming RTS will be totally blocked. To be specific, the sender

sends RTS to the receiver, but the receiver knows that someone in its neighbor is receiving packets, and it cannot reply. The sender assumes the RTS failed and backs off randomly. If the active neighbor of the receiver keeps receiving packets, the communication between the sender and receiver can be blocked for a long time, which is unfair. To overcome this problem, the request for request to send (RRTS) is introduced into the protocol. When the receiver receives RTS and cannot reply immediately, it will wait. When it overhears ACK, it will immediately send a RRTS to the sender, and the sender will reply with RTS. Then, the receiver sends CTS, and the sender can safely commence data transmission. In this case, the previously active node overhears the RRTS, and it will wait for two time slots. After this, if it hears CTS from the target receiver, that means the communication is successfully built up, and it has to wait until it is over.

It should be noted that the exposed terminal problem is not completely solved in IEEE 802.11 RTS/CTS. For example, when the sender transmits a RTS to the receiver, if the receiver is in the transmission range of another active node sending data, the RTS will collide with the data packets. As a result, the RTS is not successfully received by the receiver due to co-channel interference, and the sender will wait for the CTS until time out. Then, the sender assumes that the failure of RTS was caused by collision, and it will back off for a random time and try again. Generally, data packets are much longer than control packets, and the sender will keep trying until the RTS is successfully transmitted between transmissions of the active node. This leads to low efficiency and unfairness and is one of the flaws of this protocol.

Key Applications

Multiple access collision avoidance is key technology for any communication protocols in ad hoc networks.

Hybrid beamforming

Definition

Hybrid precoding is one of the precoding techniques to support noninterference multi-stream transmission in massive multiple-input multiple-output (MIMO) wireless communications. More explicitly, hybrid precoding is a combination of the analog precoder in the radio-frequency (RF) front end, together with the digital precoder in the baseband. A major advantage of hybrid precoding is that it consumes smaller number of up/down conversion chains than the conventional full digital precoder for MIMO systems. In hybrid precoding, the introduced analog precoder is a network of analog phase shifters, which control the phase of the signal on each transmit antenna. Therefore, hybrid precoding is capable of providing a significant precoding gain but with low hardware cost and low power consumption.

Hybrid precoding has two main structures as shown in Fig. 1 (Han et al. 2015; Molisch et al. 2017; Huang et al. 2018). In the full-complexity structure as shown in Fig. 1a, the digital signal from each transceiver can be delivered to any antenna after analog weighting. Thus, each analog precoder output can be a linear combination

of all the RF signals with a relatively high complexity. By appropriately designing the analog and digital precoders, the full-complexity structure is capable of reaching the capacity upper bound, i.e., the capacity of full digital precoder. By contrast, in the reduced-complexity structure as shown in Fig. 1b, the digital signal from each transceiver can only be delivered to a fixed number of antennas, which causes performance loss compared with the full-complexity structure. Thus, each analog precoder output can be a phase shift version of its corresponding RF signal, and the design for the analog precoder is much easier than that of its full-complexity counterpart.

Hybrid precoding scheme can also be divided into two types as full feedback and limited feedback. In the full feedback hybrid precoding scheme, the transmitter can acquire the full channel state information (CSI). Taking advantage of the full CSI, the transmitter can appropriately arrange the analog and digital precoders and provide the same performance as the full digital precoder (Bogale et al. 2016). However, since it is difficult to feedback all the channel information in massive MIMO, full CSI is hard to be directly obtained at the transmit side. Thus, the limited feedback hybrid precoding scheme was proposed (Alkhateeb et al. 2015; Liu et al. 2018). The limited feedback hybrid precoding is generally divided into three stages. At the first stage, the transmitter broadcasts all the codebook vectors in turn. At the second stage, the receiver feedbacks the indices of the selected codebook vectors based on designed criterion. At the third stage, the transmitter uses the selected codebook vectors to generate the analog and digital precoding books.

Historical Background

Massive MIMO has attracted lots of research interests due to its outstanding performance toward the downlink transmission of future wireless communications (Xiao et al. 2017; Xue et al. 2016; Cui et al. 2018). However, the large number of antenna elements in massive MIMO also poses major challenges. Most

Hybrid Precoding, Fig. 1
Two structures of hybrid precoding

important of all, a large number of RF chains are introduced, which increases the cost and energy consumption.

A promising solution to the above problem lies in the concept of hybrid transceivers, which use a combination of the analog precoder in the RF front end, together with the digital precoder in the baseband, connected to the RF with a smaller number of up/down conversion chains. Hybrid precoding was first introduced and analyzed in the mid-2000s in Zhang et al. (2005) and Sudarshan (2006). It is motivated by the fact that the number of up/down conversion chains is only lower-limited by the number of data streams, while the precoding gain and diversity order is

given by the number of antenna elements if suitable RF precoding is done.

Key Applications

The key applications of hybrid precoding include massive MIMO and cellular and millimeter wave communications.

Hyper Cellular Network: Control-Traffic Decoupled Radio Access Network Architecture

Sheng Zhou and Zhisheng Niu
Tsinghua University, Beijing, China

Synonyms

[Control-data separation](#); [Dual connectivity](#)

Definitions

Hyper cellular network is a radio access network architecture based on the separation of control coverage and traffic coverage, enabling agile coverage, elastic access, and adaptive service.

Background

A base station (BS) in traditional radio access networks (RANs) handles both the signaling control and data transmission for users in its coverage. The tight coupling of control and data transmission on a single entity makes it hard to provide flexible and energy-efficient services for RANs. To meet the increasing needs for green and elastic wireless access, new air interface architectures of cellular networks that feature signaling and data separation have been developed. Hyper cellular network architecture is one of them that aims at flexible and efficient control of small cells for throughput boosting and BS sleeping-based energy saving (NIU et al. 2012).

To realize the decoupled control-traffic coverage, separation schemes for the air interface have been recently developed in Xu et al. (2013), Zhao et al. (2015) and Jha et al. (2014). To make cell coverage more adaptive to traffic dynamics, some control signaling functions should be decoupled from the data functions so that the data traffic is served on demand, while the control plane is

always on to guarantee basic coverage. Based on functionality separation (Xu et al. 2013), a separation scheme is proposed in Zhao et al. (2015), which designed the separation of logical channels and signaling protocols in the hyper cellular network. Besides, the idea of decoupled air interface in the cellular standard is known as dual connectivity in Third Generation Partnership Project (3GPP) Long Term Evolution (LTE) Release 12 (3GPP 2013). In dual connectivity, the separation is specified in the aspects of the control plane and user plane (Jha et al. 2014).

Foundations

As illustrated in Fig. 1, the hyper cellular network decouples the air interface of RAN by separating the control coverage from the traffic coverage with two types of base stations (BSs). Control BSs (CBSs) provide the control coverage, while traffic BSs (TBSs) provide the traffic coverage. Typically CBSs have large coverage areas, within which TBSs are deployed. CBSs provide the network control for underlying TBSs and mobile users. In particular, they grant the network

access to mobile users. To guarantee a basic level of data service and to cope with high mobility users, CBSs can also be used to provide low-rate data services such as voice calls to the user equipment (UE). Unlike CBSs, TBSs are only responsible for high-rate data services. Specifically, there can be different types of TBSs to support various classes of high-rate and low-mobility data services. Through the separation, TBSs can be much more simplified than conventional BSs and can simply go to sleep whenever there is no or very few traffic within their coverages. Through this kind of sleeping control of the traffic coverage, a large amount of energy consumption can be saved because the major part of energy consumption of BSs is the basic power (baseband processing unit, amplifier, fans, etc.), which can only be saved by turning the whole BS off.

Under the separation architecture, CBSs provide centralized controls and enable dynamic operations of TBSs. CBSs and TBSs serve mobile users collaboratively. When a user equipment (UE) is powered on, it searches for nearby CBSs and registers to the network through a CBS. CBSs gather network state information such as UE locations and traffic load from UEs and TBSs

Hyper Cellular Network: Control-Traffic Decoupled Radio Access Network Architecture, Fig. 1 A sketch for the separation of control coverage and traffic coverage in hyper cellular network

underlying its coverage and thus hold a global view of the network. When high-rate data services are required, the UE sends requests to the CBS, and the CBS dispatches one or more TBSs for the requested service afterward. When the network traffic load is light, TBSs can be turned off under the command of the CBS to reduce the energy consumption of the network; in the meantime the CBS still preserves the network coverage.

To realize the decoupled architecture, network functionalities and logical channels need to be separated for different types of BSs. In hyper cellular network, CBSs are in charge of synchronization, broadcast of system information, paging, and low-rate data transmission, while TBSs are only responsible for high-rate data transmissions. The separation scheme for the logical channels is shown in Table 1, considering the corresponding network functionalities. BCCH (broadcast control channel, BCH in GSM/GPRS) and CCCH (common control channel, including PCCH for paging in UMTS and LTE) are reserved by CBSs since they are in charge of network functionalities including synchronization, paging, and broadcast of system information. CTCH (common traffic channel, TCH in GSM/GPRS, MTCH and MCCH for multicast in LTE) is also left at the CBS side to take care of low-rate data transmissions. At the TBS side, DTCH (dedicated traffic channel) and DCCH (dedicated control channel) are supported, and they are responsible for high-rate data transmissions. In the case of GSM/GPRS, PDTCH (packet data traffic channel) and PACCH (packet associated control

channel) are exploited at TBSs for packet data transmissions and associated controls.

In RANs, radio resource control (RRC) connection setup process is required between the random access and the setup of data services. Specifically in hyper cellular network, for high-rate data services, UE has access to the CBS first and then builds connection to the TBS. To this end, the RRC connection setup process needs to be modified, plus the signaling interaction between different BSs. As shown in Fig. 2, UE first sends RRC connection request message to the CBS. The CBS then forwards the message to the TBS according to a given BS dispatching algorithm. After that, the TBS sends RRC connection setup messages with channel information to the CBS, forwarding to the UE. Finally, the UE sends RRC connection setup complete message and builds the initial connection to the TBS. After the RRC connection is set up, the following procedures are similar to those in current RANs. A high-level flowchart for data services in hyper cellular network is shown in Fig. 3.

Key Applications

The decoupled structure of RAN enables many new applications and technologies for green and elastic access in wireless communications. The following are two typical applications of hyper cellular network:

- Load balancing. In hyper cellular network, the CBS can gather the information of all UEs and TBSs within its coverage and thus have a global view of the network. Based on that, the CBS can dispatch multiple TBS for load balancing, which can potentially deliver better services in addition to improving radio resource utilization and reducing the risk of system failure. To implement load balancing, the active TBSs periodically send the load information to the CBS through the backhaul link. When a new channel request arrives, the CBS decides which TBS is going to provide the service based on the load information.

Hyper Cellular Network: Control-Traffic Decoupled Radio Access Network Architecture, Table 1 Logical channel separation in hyper cellular network

cellular network

- BS sleeping-based energy saving. With the decoupled air interface, the CBS can provide an “always-on” control coverage, which enables the flexible and dynamic sleeping of TBSs without generating unwanted coverage holes. Because the CBS holds the global network information, it makes the decisions which TBSs are going to sleep based on a given BS sleeping algorithm. Researchers in Zhang et al. (2014) and Guo et al. (2016) have developed several BS sleeping algorithms and shown the benefits of BS sleeping in energy saving. To control the dynamic sleeping of TBSs, the CBS can periodically send indication messages to each TBS, based on which the TBS can decide its work state, i.e., active or sleep. The messages are transmitted through the backhaul links between the CBS and the TBSs.
- Integrating the hyper cellular concept with cloud-based RAN architecture and software-defined network technology. Cloud RAN (C-RAN) (Chih-Lin et al. 2014) consolidates baseband units (BBUs) of BSs to a centralized computing cloud while only leaving remote radio units at the network edge. With virtualization, virtual base stations (VBSs) can be realized therein for flexible RAN configurations and operations. SoftRAN (Gudipati et al. 2013) aims to enable software-defined RANs (SDRANs) by introducing a logically centralized controller and distributed radio elements. With the centralized controller, SDRAN simplifies network management by software programming. CONCERT (Liu et al. 2014) builds a converged cloud and cellular system based on control-data decoupling. Some initial efforts on realizing hyper cellular network via a software-defined approach in a cloud-based infrastructure can be found in Zhou et al. (2016), where a software-defined hyper cellular architecture (SDHCA) is proposed.
- Learning-based state control for TBSs in hyper cellular network. The optimal working

Future Directions

There are some future directions beyond the separation of the air interface in hyper cellular networks, two of which are listed as follows:

Hyper Cellular Network: Control-Traffic Decoupled Radio Access Network Architecture, Fig. 3 Flow chart of high-rate data services in hyper cellular network

states of TBSs depend on many factors, among which the channel state information (CSI) and traffic load variations are the keys. There is a fundamental difficulty to get the CSI of sleeping TBSs as no pilot is sent from them. To estimate the CSI of sleeping TBSs in order to assist the decision of potentially turning on sleeping TBSs, users can exploit the correlation among the CSI of sleeping TBSs and active TBSs or the “always-on” CBS, via learning mechanisms (Liu et al. 2015). Initial efforts of learning the CSI of sleeping TBSs from CBS equipped with multiple antennas can be found in Chen et al. (2017). In terms of traffic variations, conventional mechanism on TBS on/off

switching mostly rely on simple statistical models, e.g., Poisson models. However, real traffic largely deviates from these ideal models. To this end, model-free TBS control mechanisms based on reinforcement learning are yet to be explored.

Imprecise Computation Task Mapping on Multi-core Wireless Sensor Networks

Lei Mo, Angeliki Kritikakou, and Olivier Sentieys
Univ Rennes, INRIA, CNRS, IRISA, Rennes, Cedex, France

Synonyms

[Imprecise computations](#); [Multicore architectures](#); [Task mapping](#)

Definitions

Imprecise Computation (IC) model (Liu et al. 1994) considers that a task can be logically

decomposed into a *mandatory* subtask and an *optional* subtask. The mandatory subtask should be completed before the task's deadline in order to generate the minimum acceptable Quality of Service (QoS). The optional subtask is to be executed after the mandatory subtask, and still before the deadline, if there are resources in the system that are free to execute the optional subtask. The longer the optional subtask is executed, the better is the QoS of the obtained result.

Historical Background

Wireless Sensor Networks (WSNs) consist of a large number of wireless sensor nodes that have the capability to take various measurements of their environment. These measurements could be temperature, sound, vibration, pressure, motion, etc. *Energy efficiency* and *real-time execution* are critical and challenging issues for the design of WSNs systems (Mo et al. 2018a). This is because:

1. Most of the sensor nodes have energy constraints, as they are powered by a battery that has a limited energy budget.
2. Real-time responsiveness is required by many WSN applications, e.g., mobile target tracking. Missing of the task deadline can cause serious results.

In the past, many research works have focused on optimizing the energy efficiency and real-time execution of applications on WSNs, e.g., data aggregation (Dhasian and Balasubramanian 2013), topology control (Esch 2013), sink mobility (Silva et al. 2014), and delay-aware routing (Lai et al. 2018). These methods improved significantly the energy efficiency and real-time execution of the WSNs. However, further improvements exist:

1. Most of the past works focused on the software optimization methods without including the hardware optimization strategies.

2. Most of the past works focused on reducing the energy consumption of the wireless transmission but ignored the energy consumption of the processor modules.

However, processing and transmitting large amount of sensed data in real-time applications exceeds the capabilities of traditional WSNs. Since *single-core* embedded sensor nodes will soon be unable to meet the increasing requirements of data intensive applications, e.g., Wireless Multimedia Sensor Networks (WMSNs), the next generation sensor nodes must possess enhanced computation and communication capabilities, i.e., *multi-core* embedded sensor nodes (Munir et al. 2014). For instance, the fire detection WMSN node MiLive-v2 in (Liu et al. 2018) is equipped with three types of processors:

1. A 8-bit low-power AVR processor (ATmega128rfa1), which can be used to run simple tasks.
2. A 32-bit powerful ARM processor (ARM1176JZF), which can be used to run more complicated tasks.
3. A Digital Signal Processor (DSP) unit, which can be specially used to perform image processing.

The requirements of WSNs are usually high-performance computation, low-energy consumption, and low-task execution delay. The efficient mapping of the tasks on multi-core sensor nodes (Liu et al. 2018) is required to balance these *contradictory* requirements. It can simultaneously optimize *task allocation* (on which processor each task is executed) and *task scheduling* (when each task starts and ends its execution). On the one hand, in order to map a set of applications on multi-core system, the applications need to be partitioned (parallelized), whenever possible, into multiple tasks that can be executed concurrently on different processors. Therefore, task execution delay can be further reduced. On the other hand, multi-core systems have better energy savings than traditional single-core systems in two ways:

1. Multi-core embedded sensor nodes can extract the desired information from the sensed data and process this information. It leads to reduction in the data transmission volume sent to the sink node (base station). By replacing a large percentage of communication with in-network computation, the multi-core system realizes large energy savings that increase the sensor network's overall lifetime.
2. A multi-core embedded sensor node allows the computations to be split across multiple processors, while running each processor at a lower voltage and frequency, as compared to a single-core system, which results in energy savings. Utilizing a single-core embedded sensor node for information processing in data intensive applications demands the sensor node run at a high voltage and frequency in order to meet the application's real-time requirements. It will increase the power dissipation of the processor.

The tradeoff between energy consumption and performance has been extensively studied using the following methods:

1. *Dynamic Voltage and Frequency Scaling* (DVFS): By lowering the supply voltage, quadratic savings in dynamic energy consumption can be achieved, while the performance is approximately degraded in linear manner.
2. *Dynamic Power Management* (DPM): By exploring idle intervals of the processors and switching off a processor, when the idle interval is longer than a certain threshold, which is called break-even time.

Existing works that focus on energy-aware task mapping problem aim at minimizing the energy consumption under resource and application constraints.

1. When the voltage level is *discrete*, the task mapping problem is usually formulated as Integer Programming (IP), e.g., (Mahmood et al. 2017; Xu et al. 2012; Li and Wu 2015). To efficiently solve the IP problem, a hybrid

Genetic Algorithm (GA) is proposed in (Mahmood et al. 2017), a polynomial-time two-step heuristic is designed in (Xu et al. 2012), and the IP problem is relaxed to a Linear Programming (LP) in (Li and Wu 2015). Combining DVFS and DPM, a Mixed-Integer Linear Programming (MILP)-based task mapping problem is considered in (Chen et al. 2014) and the problem is solved by CPLEX solver.

2. When the voltage level is *continuous*, a convex task mapping problem is formulated in (Kong et al. 2011) and the problem can be solved by using polynomial-time methods. In (Leung et al. 2003), Mixed-Integer Non-Linear Programming (MINLP) is used to formulate the task mapping problem. The problem is relaxed to an MILP by linear approximation and solved by Branch and Bound (B&B) method.

As long as the resource and application constraints (e.g., task deadline) allow, the methods with DVFS or DPM achieve significant energy reductions compared to the basic methods, where no DVFS or DPM is applied.

Key Applications

In several application domains, an approximate – but still in time – result is preferable than an exact result obtained too late. For example, in audio and video streaming, frames with a lower quality are better than missing frames. In radar tracking, an estimation of target's location in time is better than an accurate location arriving too late. In control loops, an approximate result produced by a control scheme is more preferable as long as the controlled system, e.g., indoor temperature control system, remains stable. This type of applications can be modeled as *Imprecise Computation* (IC) tasks. The more cycles of the optional subtasks are executed, the higher is the generated QoS. An interesting question is how should the function of QoS be defined in order to represent realistic application areas:

1. A *linear* function (Yu et al. 2013a, b; Zhou et al. 2017; Wei et al. 2017; Mo et al. 2017, 2018b) models the case where the QoS of the overall system increases uniformly during the optional subtask execution.
2. A *concave* function (Aydin et al. 2001; Yu et al. 2008; Cortes et al. 2006; Tchamgoue et al. 2013) addresses the case where the increase of QoS exhibits a continuously nondecreasing rate as the optional subtask execution goes on.

Linear and general concave functions are considered as the most realistic and typical QoS representation in the literature, as they adequately capture the behavior of many application areas, such as image and speech processing, control engineering, and automatic target recognition (Aydin et al. 2000, 2001; Liu et al. 1994).

Foundations

The three constraints *energy*, *deadline*, and *QoS* play important roles in the QoS-aware task mapping. This is different from the energy-aware task mapping, where no exploration of the QoS improvement through the optional subtasks adjustment take place. The QoS-aware task mapping problem uses the IC task model and has a goal to maximize the QoS under a set of real-time and energy supply constraints (e.g., Aydin et al. 2001; Cortes et al. 2006; Yu et al. 2008, 2013a, b; Tchamgoue et al. 2013; Isabel et al. 2017; Zhou et al. 2017; Wei et al. 2017; Mo et al. 2017, 2018b). Specifically, QoS-aware task mapping determines on which processor should the task be executed (task-to-processor allocation), its frequency (frequency-to-task assignment), the start time (task scheduling), and the end time (optional subtask adjustment) of each task, such that the system QoS is maximized, while meeting the energy supply and the task deadlines. Usually, the task-to-processor allocation and frequency-to-task assignment decisions are *binary* variables, while the task scheduling and optional subtask adjustment

decisions can be either *integer* (Yu et al. 2008, 2013a, b; Isabel et al. 2017; Zhou et al. 2017; Wei et al. 2017) or *continuous* (Aydin et al. 2001; Cortes et al. 2006; Tchamgoue et al. 2013; Mo et al. 2017, 2018b) variables. Based on different constraints and variables introduced into the problem formulation, the variables may be coupled with each other nonlinearly, i.e., MINLP. However, it is not desirable since solving MINLP is much more complex than solving MILP. In order to linearize the nonlinear items, the common methods include:

1. Linear approximation (Leung et al. 2003).
2. Variables replacement (Chen et al. 2014; Mo et al. 2018b).

The QoS-aware task mapping problem is similar to *Quadratic Assignment Problem*, a well-known NP-hard problem. Therefore, finding an optimal solution satisfying all the given constraints (e.g., energy efficiency, deadline, QoS, task dependency, and DVFS) is very difficult and time consuming (Mo et al. 2018b). Existing works usually focus on different contexts, as summarized in Table 1. The platforms considered in (Cortes et al. 2006; Yu et al. 2008; Tchamgoue et al. 2013) are single-core platforms, i.e., the task allocation problem is not taken into account. Although the works in (Aydin et al. 2001; Yu et al. 2013a, b; Isabel et al. 2017; Zhou et al. 2017; Wei et al. 2017; Mo et al. 2017) target at multi-core platforms, some assumptions are made during the problem formulation, e.g., the task-to-processor allocation is fixed and given in advance for all the tasks in (Yu et al. 2013a, b), the tasks considered in (Isabel et al. 2017) are independent, and in (Aydin et al. 2001; Zhou et al. 2017; Wei et al. 2017; Mo et al. 2017) each processor has a predefined frequency. The methods used to solve the aforementioned problems can be classified into two main classes:

1. The first class includes the methods based on heuristics (e.g., Yu et al. 2008, 2013a, b; Isabel et al. 2017; Zhou et al. 2017; Wei et al. 2017).

	Non-optimal			✓	✓	✓	✓			✓	✓		✓	✓	✓	✓		✓

Imprecise Computation Task Mapping on Multi-core Wireless Sensor Networks, Fig. 1 The structure of Benders decomposition

2. The second class includes the methods that always produce an optimal solution (e.g., Aydin et al. 2001; Cortes et al. 2006; Tchamgoue et al. 2013; Mo et al. 2017, 2018b).

Although heuristic methods can find feasible solutions in a short amount of time, they do not provide the bounds on the solution quality. When new assumptions or constraints are taken into account they must be redeveloped, and, thus, they are not always easily extensible.

The heuristic methods mentioned above usually adopted a multi-step optimization, i.e., to decouple the variables and to determine their values in sequence. For instance, a two-step heuristic called Adaptive Task Allocation (ATA) is pro-

posed in (Zhou et al. 2017). The aim of the first step is to find a task-to-processor allocation, such that the energy consumption is minimized. With the given task allocation decision, the energy consumed to execute one task is proportional to the length of its optional subtask. Based on the given task allocation decision, the aim of the second step is to adjust the optional subtasks so as to maximize OoS under the energy supply constraint. On the other hand, in order to find the optimal solution, the common methods include:

1. Convex optimization (Aydin et al. 2001; Cortes et al. 2006).
2. Benders Decomposition (BD) (Mo et al. 2017, 2018b).

The structure of BD is shown in Fig. 1. Instead of solving the binary and the continuous variables of MILP problem simultaneously, BD technique decomposes the original problem into two smaller problems with less variables and constraints: an ILP-based *Master Problem* (MP) and a LP-based *Slave Problem* (SP), and then solves them by utilizing the solution of one in the other. By doing so, the computation time can be significantly reduced. In each iteration, the current MP is solved to determine a lower bound for the original problem along with the temporary values of the binary variables. And then the SP is solved to obtain an upper bound by utilizing the MP solution. The bounds are updated if the stopping criterion, i.e., the gap between the upper and lower bounds is smaller than a predefined threshold, is not met, and a new constraint (Benders cut) is generated using the SP solution and is added to MP in next iteration.

Definitions

Spectrum measurement is of great importance to realize the dynamic spectrum sharing framework. To construct the spectrum database, spectrum measurement is needed which measures the power of the spectrum of desired signals. Generally, this operation is performed by dedicated equipments owned by the operators. Crowdsourcing the spectrum measurement tasks to the mobile users is a promising solution to improve the accuracy of the spectrum database in a cost-efficient way.

Background

With the tremendous increase of wireless devices and applications, there is a common belief that we are facing a severe shortage of spectrum resource for wireless communications in the near future. Currently, the spectrum resources below 6 GHz is almost fully allocated to primary users (PUs) in a static and exclusive way, which is highly

inefficient. To solve the spectrum crunch, we need a paradigm shift from the static, exclusive-use framework toward a dynamic spectrum sharing framework between PUs and secondary users (SUs). One promising solution that is being widely investigated is to employ a spectrum occupancy database, which relies on propagation models to calculate the received signal strength (RSS) at any receiver location. Unfortunately, this model-based spectrum database is prone to offer inaccurate and stale spectrum availability in many circumstances, e.g., approximately 40–70% of available white space is wasted in New York City (Saeed et al. 2014).

To improve the spectrum database accuracy, real-time spectrum measurements could be incorporated into the quasi-static database. A basic approach is to deploy dedicated sensors uniformly over the region of interest (Phillips et al. 2012). However it suffers from the high cost for database operator. A practical alternative is to exploit crowdsourcing for the sensing task (Nika et al. 2014), i.e., recruiting users with mobile devices that are outfitted with spectrum sensors. However participating in a crowdsourcing task may incur additional bandwidth usage and energy consumption for mobile users, and thus rewards in the form of either money or resource are needed to encourage them to make contributions.

Incentive mechanism for crowdsourcing-based spectrum measurement has been firstly investigated by Ying et al. (2015). Their goal is to minimize the interpolation variance for all the spots of interest for a given budget. Both budget-free mechanism with a cardinality constraint and budget-feasible mechanism by using bisection method are proposed. Gao et al. (2016) proposed a game-theoretic model-based mechanism to incentivize the users with additional spectrum access opportunities. Specifically, a two-level game model is considered, in which the database conducts dynamic pricing in a first-level Stackelberg game and SUs strategically contribute to spectrum sensing in a second-level stochastic game. One limitation of these mechanisms (Ying et al. 2015; Gao et al. 2016) is that they do not take into consideration the heterogeneity of spots that needs to be augmented and thus cannot recruit users to meet

distinct interpolation requirements. In Wang et al. (2017b) proposed a fine-grained incentive mechanism for sensing augmented spectrum database by utilizing auction model Wang et al. (2017a), where users sell their location-specific spectrum measurement to the database operator. Instead of trying to augment the whole spectrum database, the spectrum sensing is only conducted on spots with poor propagation model-based estimation. In Wang et al. (2017c) proposed a barter-like exchange model to incentivize the SUs by using spectrum access right. Based on this model, a truthful reverse auction approach is adopted to select the SUs and determine the individual access time in a computational efficient way. In Chen et al. (2017) proposed a reputation-based cooperative spectrum sensing incentive framework, where the cooperation stimulation problem is modeled as an indirect reciprocity game. In the proposed framework, SUs choose how to report their sensing results to the database center and gain reputations, based on which they can access a certain amount of vacant licensed channels in the future.

Crowdsourcing Augmented Spectrum Database

In the current propagation model-based spectrum database, the location-specific RSS is calculated based on the transceiver distance information. However, the accuracy of the database is low especially in the urban areas due to the influence of buildings. For the approaches that try to completely replace the propagation model-based database by using extensive real-time sensing results, its capital expenditure and operating cost are extremely high. To this end, crowdsourcing augmented spectrum database system is proposed (architecture is illustrated in Fig. 1), which consists of a centralized spectrum database and multiple distributed users with mobile devices that are outfitted with spectrum sensors. The calibration on RSS by using real-time sensing results could only be executed in spots with poor calculation accuracy (white spots in Fig. 1), and the rest of the areas still use the propagation model-based approach. By this method, the spectrum

Incentive Mechanism for Crowdsourcing-Based Spectrum Measurement, Fig. 1 Architecture of the crowdsourcing augmented spectrum database

database accuracy could be improved with only a modest sensing effort. The spots that need crowdsourcing augmented could be separated out by using machine learning classifier, e.g., decision tree classifier in Chakraborty and Das (2014). Specifically, by exploring the features of distance from transmitter, received power, and line-of-sight (LOS) obstruction length, it is possible to learn where the database is likely to make inaccurate RSS calculations.

However, it is unlikely that a crowdsourcing participant locates exactly at the spot that the system wants to augment. Generally, the RSS for a desired spot is interpolated by using sensing measurements that are collected from surrounding users. Kriging Cressie and Cassie (1993) shows superior performance among different interpolation techniques and thus is widely utilized. Kriging is a linear regression method which uses location-specific known values to predict the unknown value in desired location. Consider that there is a random field in two dimensions and the value of that field (e.g., RSS in this entry) at a point (x_i, y_i) is $z_i = z(x_i, y_i)$. Given the values at a set of

locations $\mathcal{N} = \{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\}$, Kriging could predict the unknown value at a new location ($\hat{z}_0$) from the weighted known values as follows:

$$\hat{z}_0 = \sum_{i=1}^n \lambda_i z_i, \quad (1)$$

where λ_i is the normalized weight, i.e., $\sum_{i=1}^n \lambda_i = 1$. The optimal weights λ_i are determined by minimizing the estimation variance, i.e.:

$$\min_{\lambda_i} \text{Var}(\hat{z}_0 - z_0). \quad (2)$$

For the widely used ordinary Kriging (OK), it assumes z_i is intrinsically stationary such as:

$$E[z_i] = c \quad (3)$$

$$\text{Var}[z_i] = \sigma^2.$$

Let $\phi_{(x_0, y_0)}(\mathcal{N})$ denote the goal function in Eq. (2), which is the estimation variance at (x_0, y_0) by using the measurements at set $\mathcal{N}$. By substituting Eq. (1) into it, the following formula could be obtained:

$$\begin{aligned} \phi_{(x_0, y_0)}(\mathcal{N}) &= \text{Var} \left(\sum_{i=1}^n \lambda_i z_i - z_0 \right) \\ &= \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j C_{ij} - 2 \sum_{i=1}^n \lambda_i C_{i0} + C_{00}, \end{aligned} \quad (4)$$

where $C_{ij} = \text{Cov}(z_i, z_j)$ and $\text{Cov}()$ denotes the covariance function.

To find minimum $\phi_{(x_0, y_0)}(\mathcal{N})$, a key function, namely, *semivariogram* γ_{ij} , is introduced. γ_{ij} models the variance between two points as a function of their distance. The theoretical semivariogram is represented by

$$\gamma_{ij} = \frac{1}{2} E \left[(z_i - z_j)^2 \right]. \quad (5)$$

Based on the OK assumption in Eq. (3), γ_{ij} could be expressed as

$$\gamma_{ij} = \sigma^2 - C_{ij}. \quad (6)$$

Substituting Eq. (6) into Eq. (4), $\phi_{(x_0, y_0)}(\mathcal{N})$ could be expressed by using semivariogram γ_{ij} as

$$\phi_{(x_0, y_0)}(\mathcal{N}) = 2 \sum_{i=1}^n \lambda_i \gamma_{i0} - \sum_{i=1}^n \sum_{j=1}^n \lambda_i \lambda_j \gamma_{ij} - \gamma_{00}. \quad (7)$$

By using Lagrange multiplier method, the minimization problem in Eq. (7) leads to solve the following matrix equation:

$$\begin{bmatrix} \gamma_{11} & \gamma_{12} & \dots & \gamma_{1n} & 1 \\ \gamma_{21} & \gamma_{22} & \dots & \gamma_{2n} & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \gamma_{n1} & \gamma_{n2} & \dots & \gamma_{nn} & 1 \\ 1 & 1 & \dots & 1 & 0 \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \vdots \\ \lambda_n \\ \mu \end{bmatrix} = \begin{bmatrix} \gamma_{10} \\ \gamma_{20} \\ \vdots \\ \gamma_{n0} \\ 1 \end{bmatrix} \quad (8)$$

where μ is the Lagrange parameter. Obviously, the optimal weight λ_i could be obtained if semivariogram γ_{ij} is known. In practice, γ_{ij} is estimated from measurements and then fitted with empirical curve, e.g., exponential or spherical model. The minimized $\phi_{(x_0, y_0)}(\mathcal{N})$ represents the estimation uncertainty at an unmeasured location (x_0, y_0) by using measurements at set $\mathcal{N}$, which could be used as a criterion in incentive mechanism design.

Incentive Mechanism

In this subsection, we introduce two kinds of incentive mechanisms for crowdsourcing-based spectrum measurement by using monetary reward and barter-like resource exchange, respectively. The considered network consists of a set of mobile users $\mathcal{N}$ with user index i , who knows its current location (x_i, y_i) . The set of spots that needs to be augmented (i.e., interpolated) by sensing results is denoted by $\mathcal{M}$ with spot index j . The result of interpolation is quantified by the Kriging estimation variance, e.g., the estimation variance at spot j by the interpolation of the user set $\mathcal{N}$ is denoted as $\phi_j(\mathcal{N})$. The spectrum database acquires the sensing data from users periodically. The set of spots that needs to be interpolated varies at each period. At the beginning of a period, the spectrum database

announces a sensing request with the center frequency information. Notice that the request does not need to contain the location information of the spots. Upon receiving the request, interested user i competes for this crowdsourcing task by submitting its location information (x_i, y_i) . The database selects a winner set $\mathcal{W}$ ($\mathcal{W} \subseteq \mathcal{N}$) to perform the crowdsourcing, and accordingly the informed winners report their sensing measurements to the database.

Monetary Reward-Based Incentive Mechanism

While participating in crowdsourcing, there is a cost c_i occurring to user i , which is related to the additional bandwidth usage and energy consumption. Notice that the cost is a private information and thus is only known by the user itself. If user could receive a monetary reward p_i from the database which is higher than its cost c_i , user i would have the incentive to participate in the crowdsourcing task. Therefore, based on the assumption that the users are rational, they are always trying to maximize their utility which could be defined as follows:

$$u_i = \begin{cases} p_i - c_i, & i \in \mathcal{W} \\ 0, & \text{otherwise.} \end{cases} \quad (9)$$

In a fine-grained system, each augmented spot j may have an estimation quality requirement r_j . r_j could be quantified by the Kriging estimation variance, that is, spot j 's RSS needs to be interpolated with a maximum estimation variance r_j . Therefore, the considered problem could be formulated as the following optimization problem:

$$\begin{aligned} & \min_{i \in \mathcal{W}} c_i \\ & \text{subject to } \phi_j(\mathcal{W}) \leq r_j, \forall j \in \mathcal{M}. \end{aligned} \quad (10)$$

where the objective function is to minimize the total costs of the selected user set $\mathcal{W}$ for crowdsourcing and the constraint function ensures that the quality requirement for each spot is met, i.e., the estimation variance at spot j by the interpolation of the winner set $\phi_j(\mathcal{W})$

is no larger than j 's requirement. The considered minimization problem is equivalent to the subset selection problem, which is proven to be NP-hard. Therefore, it is impossible to compute the optimal set of selected users that minimizes the total costs in polynomial time.

To solve this problem in an efficient way, an auction-based mechanism could be used (Wang et al. 2017b). Specifically, the database acts as a buyer who wants to buy measurement data, and the users act as sellers. Along with the location information, interested users also send bid b_i to the database, which may or may not be its real cost c_i . The mechanism consists of two phases:

winner selection and *payment determination*. Winner selection algorithm is based on the greedy heuristics that keeps selecting the next user with most *cost-efficient contribution* until all the spots' requirements are met. The cost-efficient contribution of user i changes according to the current winner set $\mathcal{W}$, which is defined as

$$\alpha_i(\mathcal{W}) = \frac{m_i(\mathcal{W})}{b_i}, \quad (11)$$

where b_i is i 's bid and $m_i(\mathcal{W})$ is i 's *total weighted marginal contribution* based on the current $\mathcal{W}$. $m_i(\mathcal{W})$ is calculated by

$$m_i(\mathcal{W}) = \sum_{j \in \mathcal{M}} \frac{\max(\phi_j(\mathcal{W}), r_j) - \max(\phi_j(\mathcal{W} \cup \{i\}), r_j)}{r_j}, \quad (12)$$

Here, the numerator $\max(\phi_j(\mathcal{W}), r_j) - \max(\phi_j(\mathcal{W} \cup \{i\}), r_j)$ could be regarded as the "marginal contribution" of user i to spot j under the current winner set $\mathcal{W}$. And this marginal contribution is weighted by $1/r_j$, i.e., the spot with small variance requirement has large weight.

To determine the payment, the key point is to find the maximum bid each winner can submit that allows it to win, i.e., critical payment. By using the critical payment, the auction mechanism could be proven to be truthful. Truthful is one of the most important properties that an auction mechanism desires, since in a truthful auction, bidding the true cost ($b_i = c_i$) is the dominant strategy regardless of other users' strategies. Specifically, to find the critical payment for winner k , the payment determination algorithm repeats the winner selection algorithm for the user set without k , i.e., $\mathcal{N}' = \mathcal{N} \setminus \{k\}$. In set $\mathcal{N}'$, the mechanism finds the winner l' who has the maximum $\alpha_{l'}(\mathcal{W}')$ based on the current winner set $\mathcal{W}'$. To let winner k replace winner l' , its cost-efficient contribution needs to be larger than that of l' , that is:

$$\frac{m_k(\mathcal{W}')}{b_k} > \frac{m_{l'}(\mathcal{W}')}{b_{l'}}. \quad (13)$$

In other words, the maximum bid for winner k that lets it replace winner l' is $\frac{m_k(\mathcal{W}')}{m_{l'}(\mathcal{W}')} \cdot b_{l'}$. Eventually, the maximum of these values is used as the critical payment for k .

Barter-Like Resource Exchange-Based Incentive Mechanism

It is assumed that the database incentivize users by using a nonmonetary payment p_i which is in the form of additional channel access time. And each user that participates the crowdsourcing task has a desired channel access time, which is denoted by t_i . Notice that t_i is a private information and thus is only known by the user itself. The length of each round that the database operator wants to collect new measurements is T , during which the selected users could share the channel access in a TDMA fashion. The rational user always tries to maximize its utility, which is defined as

$$u_i = \begin{cases} p_i - t_i, & i \in \mathcal{W} \\ 0, & \text{otherwise.} \end{cases} \quad (14)$$

Therefore, the considered problem could be formulated as the following optimization problem:

$$\begin{aligned} & \min_{\mathcal{W}} \sum_{j \in \mathcal{M}} \phi_j(\mathcal{W}) \\ & \text{subject to} \quad \sum_{i \in \mathcal{W}} p_i \leq T, \end{aligned} \quad (15)$$

where the objective function is to minimize the total Kriging variance for spot set $\mathcal{M}$ by the interpolation of selected winner set $\mathcal{W}$, and the constraint ensures that the sum of the payment for winner set $\mathcal{W}$ does not exceed the time interval T . Similar to Eq. (1), this optimization problem is NP-hard, and an auction-based mechanism could solve it in an efficient way (Wang et al. 2017c).

The mechanism consists of three phases, i.e., winner selection, payment determination, and bidding threshold search. Winner selection algorithm is based on the greedy heuristics that keeps selecting the next user with highest *contribution-bidding ratio* until the total bids exceed the current *bidding threshold*. The bidding threshold is related to the time interval T , which could be found by employing a bisection searching method. The contribution-bidding ratio of user i based on the current winner set $\mathcal{W}$ is defined as

$$\alpha_i(\mathcal{W}) = \frac{c_i(\mathcal{W})}{b_i}, \quad (16)$$

where b_i is i 's bid and $c_i(\mathcal{W})$ is i 's *interpolation variance contribution* based on the current $\mathcal{W}$. $c_i(\mathcal{W})$ is calculated by

$$c_i(\mathcal{W}) = \sum_{j \in \mathcal{M}} (\phi_j(\mathcal{W}) - \phi_j(\mathcal{W} \cup \{i\})). \quad (17)$$

To find the critical payment for winner k , the winner selection algorithm for the user set without k is repeated, i.e., $\mathcal{N}' = \mathcal{N} \setminus \{k\}$. In set $\mathcal{N}'$, the winner k' could be found who has the maximum $\alpha_{k'}(\mathcal{W}')$ based on the current winner set $\mathcal{W}'$. To let winner k replace winner k' , its contribution-bidding ratio needs to be larger than that of k' , that is:

$$\alpha_k(\mathcal{W}') = \frac{c_k(\mathcal{W}')}{b_k} > \alpha_{k'}(\mathcal{W}') = \frac{c_{k'}(\mathcal{W}')}{b_{k'}}. \quad (18)$$

In other words, the maximum bid for winner k that lets it replace winner k' is $\frac{c_k(\mathcal{W}')}{c_{k'}(\mathcal{W}')} \cdot b_{k'}$. Eventually, after finishing the winner selection loop on user set $\mathcal{N}'$, the maximum of these values is used as the critical payment for k .

In a truthful auction, generally the final total payments are larger than the sum of winners' bids. The final total payment is constrained by the time interval T . However, it is impossible to use constraint T to control the winner selection process, since the payment is determined after the selection of winners. Therefore, it is required to define a bidding threshold H to control the winner selection loop, i.e., the sum of the bids for all winners should not exceed this threshold. Obviously, the bidding threshold is smaller than the time constraint T , and using a bisection searching method could find it. Specifically, a lower bound l and an upper bound u are used to narrow down the possible range of the bidding threshold, and a tolerance e is employed to stop the searching process.

Key Applications

The crowdsourcing-based spectrum measurements are crucial for the dynamic spectrum sharing. Due to the tremendous increasing of mobile data traffic, dynamic and efficient spectrum sharing mechanism is required. To realize interference protection and reuse the whitespace efficiently, an accurate spectrum database that using crowdsourced spectrum measurement is promising.

Incentive Mechanisms for Mobile Crowdsensing

Incentive mechanisms for mobile data crowdsourcing

Definition

Incentive mechanisms incentivize mobile users to behave as desired by the requester of mobile crowdsensing

Background

Mobile crowdsensing has found a wide range of applications, such as spectrum sensing (Ding et al. 2014) and environmental monitoring (e.g., air quality Mun et al. (2009), noise level Rana et al. (2010), and weather conditions Atmos (2014) like temperature, humidity, and wind speed). In principle, crowdsensing (For brevity, we call “mobile crowdsensing” as “crowdsensing”) leverages the “wisdom” of a potentially large crowd of mobile users by allocating a sensing task to them and collecting the data from them for the task. The popularity of crowdsensing is promoted by powerful mobile devices equipped with various sensors and pervasive Internet connectivity. This trend is expected to grow in the foreseeable future with the emerging Internet of Things (IoT). With enormous opportunities brought by big data, crowdsensing serves as an important first step for data mining tools to harness the power of big data in many application domains.

Although the benefit of crowdsensing is pronounced, performing a sensing task typically incurs overhead for the participating user, in terms of the user’s resource consumption devoted

to sensing, such as battery and computing power. Further, the participating user also incurs the risk of potential privacy loss by sharing its sensed data with others. In general, a user may not participate in sensing without receiving adequate incentive. Therefore, effective incentive design is essential for realizing the benefit of crowdsensing.

Overview

The past few years have seen many studies on incentive mechanisms for crowdsensing (see, e.g., Duan et al. 2012; Shah and Zhou 2015; Wang et al. 2016). Most of these works use monetary reward to stimulate users' participation, where the crowdsensing requester pays some money to a user for participating in crowdsensing. A well-known real-world example is Amazon Mechanical Turk (MTurk), where a user receives payment (e.g., \$0.2) for completing a crowdsensing task. Another class of incentive mechanisms (e.g., see Luo and Tham 2012; Gong et al. 2015) exploits users' service to stimulate users' participation. In this situation, a user acts as both a contributor and a consumer, such that the service it receives as the consumer compensates the service it provides as the contributor. A typical real example is traffic monitoring (e.g., Google Maps, Waze), where a user provides its location which is used to estimate real-time traffic information, while the user itself also receives this information estimated from the locations provided by other users. Social relationships have also been exploited Gong et al. (2015) to incentivize users to perform crowdsensing tasks for their social friends, as users are typically altruistic to their social friends. In this article, we focus on incentive mechanisms based on monetary reward.

A key challenge in the incentive design for crowdsensing is that a user may have private information (e.g., cost, data, quality) or hidden actions (e.g., effort) which is unknown to and cannot be verified by the crowdsourcing requester. As a result, a strategic user may have incentive to manipulate its private information revealed to the requester or its hidden actions,

so as to gain an advantage. In the following, we will discuss truthful mechanisms that incentivize users to truthfully report their private information to the requester and take hidden actions as desired by the requester.

Classification of Truthful Mechanisms

Truthful Mechanisms for Cost Elicitation

There have been many mechanisms to incentivize users to truthfully reveal their cost of participation in crowdsensing (e.g., see Yang et al. 2012; Koutsopoulos 2013; Tarable et al. 2015; Luo et al. 2015). The cost is considered to be a strategic user's private information that it would not be willing to reveal truthfully to the user's advantage without appropriate incentive. Intuitively, a user would overreport its cost to the requester, in the hope of receiving a higher reward to compensate its cost. Most incentive design problems in this category are formulated as a reverse auction, where the requester is the auctioneer who pays users for performing crowdsensing tasks. Some studies (Zhang et al. 2016; Jin et al. 2017a) have considered a double auction where there are multiple requesters with multiple tasks for users to perform. Some other studies (Subramanian et al. 2015; Han et al. 2016, 2017) have considered an online auction where users arrive and leave sequentially in time. As a major characteristic of mobile crowdsensing, the locations and mobility of users have been taken into account explicitly in some works (Feng et al. 2014; Zhang et al. 2016). Many existing mechanisms for cost elicitation have been designed based on the classical VCG auction and the characterization of truthful mechanisms (Nisan et al. 2007, Theorem 9.36).

Truthful Mechanisms for Effort Elicitation

Incentive mechanisms for hidden actions have been well studied in the economics literature (Bolton and Dewatripont 2005). These studies are often concerned with strategic agents that can make hidden effort that are not desired by a principal who employs the agents to work on a task. Intuitively, a user would make less effort in the task so as to reduce its cost incurred

in the task. There are a few recent studies that have investigated this problem in the context of data crowdsourcing (Cai et al. 2015; Luo et al. 2015; Jin et al. 2017b). Cai et al. (2015) have proposed truthful mechanisms to incentivize users to make efforts as desired in statistical estimation. However, most of the work on truthful elicitation of effort do not take into consideration agents' other possible private information (e.g., quality, cost). Luo et al. (2015) have designed mechanisms that not only elicit desired efforts from users but also truthful revelation of their private cost and data. Liu and Chen (2016b, 2017) has designed effort elicitation mechanisms for workers with diverse cost and studied the optimal reward for maximizing the requester's payoff. Liu and Chen (2016a) has designed a bandit-based mechanism for sequential effort elicitation.

Truthful Mechanisms for Data Elicitation

Mechanism design for truthful elicitation of strategic agents' data (e.g., opinions) has been extensively studied in various applications (Prelec 2004; Miller et al. 2005), more recently in the context of data crowdsourcing (Dasgupta and Ghosh 2013; Luo et al. 2015). The data of an agent can be its private information that it can manipulate in favor of its benefit. To protect users' privacy, one effective method is to add noise to the data reported by users, based on some privacy metric (e.g., differential privacy). Some works (Wang et al. 2016) have studied mechanisms that incentivize users to report data of a privacy level desired by the requester.

Truthful Mechanisms for Quality Elicitation

Data accuracy is a key performance metric of crowdsourcing. This is determined by the quality of the individual user's data contributed to the task, which captures the accuracy of the user's data compared to the ground truth. In general, the quality of users' data varies for different users depending on a user's specific situation (e.g., location, environment). Intuitively, a user would overreport its quality to the requester, in the hope of receiving a higher reward for contributing

high-quality data. To fully exploit the potential of crowdsourcing, it is important to perform task allocation and data aggregation based on users' data quality. Incentive mechanisms for quality-based crowdsensing have been studied in a few works (Koutsopoulos 2013; Shah and Zhou 2015; Liu and Liu 2015; Jin et al. 2015, 2016, 2017a). One interesting line of work (Jin et al. 2015, 2016, 2017a) in this direction has studied truthful mechanisms for quality-based task allocation where workers have private participating cost. Recent works (Gong and Shroff 2017, 2018) have proposed a quality-aware crowdsourcing framework and devised truthful mechanisms that incentivize users to truthfully report their quality and data to the requester and make effort desired by the requester.

Definition

Index modulation (IM) refers to a family of modulation techniques that rely on the activation states of some resources/building blocks for information embedding. The resources/building blocks can be either physical, e.g., antenna, sub-carrier, time slot, and frequency carrier, or virtual, e.g., virtual parallel channels, signal constellation, space-time matrix, and antenna activation order. A distinct feature of IM is that part of the information is implicitly embedded into the transmitted signal.

Historical Background

Wireless communications are the fastest growing segment of the communications industry. From around 1980 to the present, the wireless systems have traveled through 1st generation (1G), 2G, and 3G. Recently, the long-term evolution (LTE) and its extension, LTE-advanced (LTE-A), as practical 4G systems, are steadily expanding across global markets. Nowadays, 5G of wireless networks, which is expected to be introduced around 2020, has been one of the hottest topics in the wireless communications community over the past few years. Although there is an ongoing debate on 5G wireless technology whether it will be a simple evolution compared to its fourth generation (4G) counterpart or a radically new communication network, 5G wireless networks are expected to provide immense bandwidth and much higher data rates with considerably lower latency. However, the currently employed modulation techniques based on multi-input-multi-output orthogonal frequency division multiplexing (MIMO-OFDM), unfortunately, are not sufficient in satisfying such 5G requirements. Conventional MIMO may achieve high spectrum efficiency (SE) with massive antennas but has compromised energy efficiency (EE) due to the scaled power consumption of a large number of radio-frequency (RF) chains. The OFDM modulation is prone to Doppler-induced intercarrier interference (ICI). Its inherent high peak-to-average power ratio (PAPR) also necessitates expensive power amplifiers. Novel advanced modulation techniques are therefore very much needed. To this end, the recently emerging IM techniques arise as a promising candidate that has the potential to meet the 5G requirements.

Foundations

Existing IM schemes are mainly carried out in space, time, and frequency slots or the combination of them, among which the most marked similarity lies in the utilization of the active radio

resources to carry information. Generally speaking, IM splits the information bits into index bits and constellation bits, where the former determine which portion of the radio resources (antennas, subcarriers, etc.) is active and the latter are mapped to conventional constellation symbols that are to be carried by the active resources. Specifically, the index mapping of existing IM schemes in different domains is classified as follows:

- *IM in Space.* Spatial modulation (SM) is a representative IM technique in the space domain, which works with a single RF chain and conveys information via the antenna index (Cheng et al. 2018; Mesleh et al. 2008; Di Renzo et al. 2014). The SM signal constellation consists of (1) the conventional quadrature amplitude modulation constellation and (2) the antenna index constellation. Conveying information via the active antenna index, SM enjoys spatial multiplexing gain with a single-RF chain transmitter. Hence, SM is more energy efficient, and its detection complexity is relatively lower. Note that one drawback of SM is that the information conveyed by the antenna index increases in $\log_2 N_t$, where N_t is the number of transmit antennas. When N_t is large, SM suffers from compromised SE. The idea of SM can also accommodate multiple active transmit antennas to improve SE, giving rise to generalized SM (G-SM) (Younis et al. 2010; Wang et al. 2012). However, it requires multiple RF chains and induces inter-channel interference.
- *IM in the Space-Time.* Transmitting signals across multiple time slots facilitate transmit diversity in MIMO systems. Previous focus was on space-time matrix designs that strike the largest coding and diversity gains with satisfactory receiver complexity. Recently, interests shift the exploration of the space-time resource to convey information. Differential SM (D-SM), an IM technique in the space-time domain, is a representative example (Bian et al. 2015). The index mapping of D-SM determines the current antenna activation order according to that in the former space-time block and the current index bits. As a differential solution to SM, D-SM avoids the challenging channel estimation inherent to SM. Like SM, D-SM operates with a single RF chain but bypasses the accurate estimation of the channel state information (CSI) that is computationally demanding.
- *IM in Frequency.* OFDM-IM is a representative IM technique in the frequency domain, which extends the SM principle to OFDM subcarriers (Frenger et al. 1999; Abualhiga et al. 2009; Basar et al. 2013). In OFDM-IM, not all subcarriers carry information symbols, and the indices of inactive subcarriers convey information via IM. To date, several works have demonstrated that OFDM-IM can outperform plain OFDM in terms of the bit error rate (BER) under the same SE. It is revealed by Basar et al. (2013) that (1) OFDM-IM achieves the maximum rate if and only if the subcarriers within each group experience independent fading via, e.g., interleaved grouping; (2) OFDM-IM with interleaved grouping can achieve an up to 3 dB signal-to-noise (SNR) gain over plain OFDM for small modulation cardinality M (typically 2, 4), though this improvement becomes smaller and even diminishes as M grows; and (3) the advantage of OFDM-IM over plain OFDM can be maximized by choosing a specific number of inactive subcarriers (typically 1, or 2).
- *IM in Space-Frequency.* MIMO-OFDM has already been widely accepted as one fundamental technique in current wireless communication systems. To incorporate IM into MIMO-OFDM, one straightforward way is to carry out conventional modulation in one domain (space or frequency/subcarrier) and superimpose IM in the other domain. For example, using all subcarriers while implementing independent SM per subcarrier leads to OFDM-SM, whereas using all antennas but implementing independent subcarrier activation per each antenna would result in MIMO-OFDM with IM (MIMO-OFDM-IM) (Basar et al. 2016).

Instead of treating space and frequency domains independently, generalized space-frequency IM (GSFIM) (Datta et al. 2016) is proposed to jointly select the active elements. In GSFIM, a group of transmit antennas are activated by the information bits, and the active space-frequency elements are then jointly selected according to the remaining information bits. Therefore, it is the generalization of OFDM-SM and MIMO-OFDM-IM.

Based on the fundamental concept of IM in the space, time, and frequency, various articles aim at the improvement of the SE/EE, the potential of transmit diversity, precoding, and other enhancements of current IM techniques. Due to the similarity among different IM techniques, the enhancements proposed for a specific scheme are usually applicable to all IM techniques. To better illustrate these, three typical enhancements designed for SM, which can be readily generalized to other IM schemes, are introduced in the following.

In-Phase/Quadrature IM

The RF signals usually contain the in-phase component and the quadrature component. The orthogonality between them can be exploited to improve the SE of IM techniques. For example, given a symbol drawn from the PSK/QAM constellation, one may map its real part with a cosine carrier into a randomly selected antenna and its imaginary part with a sine carrier to another randomly selected antenna. This technique, termed as quadrature SM (QSM) (Mesleh et al. 2015), retains the requirement of a single RF chain while allowing more spatial bits to be transmitted. The frequency domain counterpart of OFDM-IM in-phase/quadrature (OFDM-IM-IQ) is shown to have significantly better error performance than IM-OFDM at the same SE (Fan et al. 2015).

Precoded IM

IM is not limited to a transmitter design. With transmitter-side CSI, effective precoding techniques, such as zero-forcing and MMSE

precoders, can facilitate parallel interference-free channels at the receive antennas. Therefore, IM techniques can be transplanted to the receiver side. By selecting the active receive antenna indices, precoding-aided SM (PSM) has been proposed by Stavridis et al. (2016). Different from SM/G-SM, the detection of the constellation symbols at different antennas can be performed in a parallel manner, therefore significantly reducing the receiver complexity especially when multiple antennas are activated. Also, in order to bypass channel estimation in PSM, D-SM can also be applied at the receiver side, which also induces 3dB performance penalty. IM in the space-frequency domain can also be applied at the receiver via precoding. With precoding, the received signals at different receive antennas are free of interchannel interference. As a result, the joint selection of the active elements in space and frequency domains will not increase the detection complexity as at the transmitter side, which will allow more flexible grouping across the space and frequency domain to reduce the intragroup channel correlation and consequently improve the error performance.

Diversity-Enhancing IM

Beside the SE improvement and the receiver complexity reduction, research has been dedicated to the error performance enhancement of IM. Among these, diversity-enhancing IM schemes are attracting increasing interests. Since IM are naturally applicable to multiple resources (antennas/subcarriers), some well-known space-time block codes (STBC), such as Alamouti, can be integrated by carefully designing the mapping of index bits. For example, STBC-SM is proposed to exploit the transmit diversity by integrating STBC technique (Basar et al. 2011). Such designs are usually migratable among different IM schemes given similar channel properties. Specifically, the coordinate interleaving method proposed for IM-OFDM is also applicable to all precoded IM schemes, because, with precoding, the received signal among the receive antennas becomes interference-free.

Practical Issues for IM

Practical implementation issues for IM are demonstrated in possible application areas. More specifically, we focus our attention into underwater acoustic (UWA), vehicle to everything (V2X), and wireless-powered (WP) communications. The concept of activating partial subcarriers during the transmission of an OFDM symbol endows OFDM-IM and its variants with potential of adaptation to high mobility scenarios, such as V2X and UWA communications, since the power of the Doppler-induced ICI, which scales with the number of active subcarriers, will be significantly reduced.

The first attempt on applying OFDM-IM to V2X communications was made by Cheng et al. (2014), where great benefits of OFDM-IM with interleaved grouping in terms of BER and achievable rate performance are revealed via analytical and simulated comparisons with classical OFDM and OFDM-IM with localized grouping. Altalib et al. (2017) investigated the performance of OFDM-IM with all SAPs encoded in a V2X scenario and demonstrated that OFDM-IM can be considered as a strong candidate for the transmission technique of the vehicular communications standard.

The first application of OFDM-IM to UWA communications was reported by Wen et al. (2014). Noticing that the power leakage from the active subcarriers to the inactive ones because of ICI significantly increases the possibility of erroneous detection of subcarrier states, Wen et al. (2014) proposed a solution by integrating the well-known ICI self-cancellation techniques into the OFDM-IM framework. With a simple modification, OFDM-IM is shown to be very effective in ICI mitigation by both computer simulations and sea experiments. The integration idea proposed by Wen et al. (2014) is generalized by Wen et al. (2016), where both the one-path and two-path implementations are demonstrated. In addition, a hybrid OFDM-IM system with improved spectral efficiency, which introduces an additional bit to indicate the OFDM-IM mode or the classical OFDM mode, is proposed.

On the other hand, the SM concept is first applied at the wireless device into a WP communication system for information transmission (IT) by mapping information to the active antenna indices (Zhang and Cheng 2017). To be specific, this novel scheme enjoys the advantages of improved system achievable rate (AR), energy harvesting (EH) and information transmission (IT), and self-energy recycling

Index Modulation, Table 1 Comparison of existing IM schemes

Scheme	RF chain number	SE	TX/RX complexity	Diversity order	CSIT/CSIR	Key advantage
SM	1	Low	Low/Low	N_r	No/Yes	High EE
D-SM	1	Low	Low/Low	N_r	No/No	Bypass channel estimation and high SE
G-SM	$< N_t$	Medium	Medium/Medium	N_r	No/Yes	Flexibly SE
PSM	N_t	Low	High/Low	$N_t - N_r + 1$	Yes/Yes	Low Rx complexity
QSM	1	Medium	Low/Low	N_r	No/Yes	Moderate SE and EE
STBC-SM	2	Medium	Medium/Medium	$2N_r$	No/Yes	High reliability and moderate EE
OFDM-IM	1	Medium	Low/Low	N_r	No/Yes	High EE
OFDM-IM-IQ	1	Medium	Medium/Medium	N_r	No/Yes	High EE and moderate SE
MIMO-OFDM-IM	N_t	High	High/High	N_r	No/Yes	High EE and moderate SE
GSFIM	N_t	Medium	High/High	N_r	No/Yes	Flexible SE

N_t is the number of transmit antennas;

N_r is the number of receive antennas

(SE-R) while requiring no backhaul links between the WD and the information receiver.

Discussion

In order to comprehensively compare existing IM schemes, Table 1 gathers the RF chain number, SE, TX/RX complexity (computational complexity for encoding and decoding at the transmit/receive side), diversity order, CSI requirement, and key advantages of the schemes. One can conclude from the table that IM improves the system EE in terms of the hardware cost, computational complexity, and error performance and increases the SE by exploiting the potential of indexing in all available domains. Please refer to the article written by Wen et al. (2017) for details about IM.

Key Applications

Index modulation is accessed in applications related to several facets, such as massive MIMO, full duplex communication, cooperative communication, high-mobility scenarios, wireless-powered communications, visible light communication, and the Internet of Things.

Index Modulation for OFDM

Jinho Choi

School of Information Technology, Deakin University, Burwood, Australia

Synonyms

Message-driven frequency hopping; Multicarrier index keying with orthogonal frequency division multiplexing; Subcarrier-index modulation aided orthogonal frequency division multiplexing

Definitions

A modulation technique that can convey multiple information bits through the index set of active subcarriers in addition to conventional signal constellations of active subcarriers in an orthogonal frequency division multiplexing (OFDM) system.

Historical Background

Index modulation (IM) can be seen as a generalization of spatial modulation (SM) (Mesleh et al. 2008) that is proposed for multiple input-multiple output (MIMO) systems. In SM, multiple bits can be transmitted by activating a subset of transmit antennas, where the indices of active antennas represent multiple information bits. If there are n_T transmit antennas and K antennas (among n_T) can be activated at a time, there are $\binom{n_T}{K}$ possible combinations, and the number of bits that can be transmitted is $\lfloor \log_2 \binom{n_T}{K} \rfloor$, where $\lfloor x \rfloor$ represents

the largest integer that is smaller than or equal to x . Furthermore, a conventional modulation can also be employed for each active antenna to transmit more bits. In Abu-alhiga and Haas (2009) and Basar et al. (2013), the concept of SM is applied to OFDM, which is called OFDM with IM or OFDM-IM. In OFDM-IM, a subset of subcarriers are active, and their indices are used to convey information. The main advantage of OFDM-IM over conventional OFDM is the energy efficiency and robustness against inter-carrier interference (ICI) as a fraction of subcarriers are active (Xiao et al. 2014). Extensions of OFDM-IM are discussed in Fan et al. (2015) where the number of active subcarriers for each sub-block is not fixed, but variable to increase the number of bits to be transmitted by a sub-block. In addition, another scheme that independently applies IM to in-phase and quadrature phase components of complex symbols is considered to increase the number of bits per sub-block.

A similar idea to OFDM-IM is message-driven frequency hopping (MDFH) (Ling and Li 2009), which might be seen as a generalization of frequency shift keying (FSK). From this point of view, the root of OFDM-IM can also be found in FSK.

Foundations

OFDM-IM is a modulation technique that conveys information by the index set of active subcarriers in addition to conventional modulation for active subcarriers. If the number of subcarriers is N and K of them are active at a time, the number of bits that can be represented by the set of active subcarriers is $\lfloor \log_2 \binom{N}{K} \rfloor + K \log_2 M$, where M is the size of constellation of conventional modulation for active subcarriers. For example, if 8-phase shift keying (PSK) is used as conventional modulation for active subcarriers, and $(N, K) = (8, 2)$, the number of bits transmitted by OFDM-IM becomes $\lfloor \log_2 \binom{8}{2} \rfloor + 2 \log_2 8 = 10$ bits. For comparison, if we consider conventional OFDM where all subcarriers are active with 8-PSK modulation, the

number of bits is $8 \log_2 8 = 24$ bits. Although conventional OFDM can transmit more bits than OFDM-IM (by a factor of $24/10 = 2.4$), the symbol energy of OFDM is higher than that of OFDM-IM by a factor of $8/2 = 4$. Thus, OFDM-IM could be more energy efficient than OFDM.

Compared to SM, OFDM-IM can be more flexible as the number of subcarriers, denoted by N_F , can be large (e.g., $N_F = 512, 1024$, or 2048). However, if N_F is large, there might be too many combinations for the set of active subcarriers, which makes the implementation of OFDM-IM difficult in terms of detection. Thus, subcarriers are divided into multiple sub-blocks, where the size of sub-block is usually small (e.g., 4, 8, or 16) and OFDM-IM is independently performed for each sub-block (Basar et al. 2013).

The diversity order of OFDM-IM under Rayleigh fading is limited (Basar et al. 2013; Ko 2014), which is inherited by OFDM. In OFDM-IM, a data symbol through an active subcarrier experiences fading, and the detection performance of the data symbol is limited by deep fading. In order to increase the diversity gain, the notion of space-time coding can be employed as in Basar (2015b), where in-phase and quadrature phase components of an active subcarrier can come from different symbols with constellation rotation (Khan and Rajan 2006). Channel coding helps improve the diversity gain with a transmit diversity technique (Choi 2017). In general, there are multiple sub-blocks, and each sub-block can be seen as a modulated symbol (by IM). Then, the notion of trellis-coded modulation (TCM) (Ungerboeck 1982) can be employed to increase the signal distance over a sequence of IM symbols with a channel encoder. As a result, the performance can be improved by coding gain as well as diversity gain (Choi and Ko 2018).

As conventional OFDM, OFDM-IM can be applied to MIMO systems. For example, each antenna can transmit independently modulated signals as in Basar (2015a). It is also possible to combine OFDM-IM with SM as in Datta et al. (2016), which can be seen as IM in the frequency

and space domains. Therefore, there can be a number of possible ways to implement MIMO-OFDM-IM.

In OFDM, due to Doppler effect and carrier frequency offset (CFO), the orthogonality of subcarriers can be broken, which results in ICI and degrades the performance. While all the subcarriers are active in OFDM, a fraction of the subcarriers are active in OFDM-IM. As a result, the performance degradation due to ICI in OFDM-IM is lower than that in OFDM (Xiao et al. 2014). This feature makes OFDM-IM appealing to wireless communications that suffer from high Doppler effect and CFO.

Key Applications

For underwater acoustic communications (UAC), OFDM-IM is considered in Wen et al. (2016) to mitigate channel dispersion. Compared to OFDM, OFDM-IM has a low ICI which makes it suitable for UAC where the performance can be degraded by ICI due to inevitable Doppler effect. Due to the same reason, OFDM-IM can also be used for vehicle-to-vehicle and vehicle-to-infrastructure (V2X) applications (Cheng et al. 2014) and would be a favorable modulation scheme for unmanned aerial vehicle (UAV) communications.

Future Directions

The principles of IM can also be applied to multiple access for multiuser systems. That is, the index set of active subcarriers can be used to differentiate users in a multiuser system as sparse code multiple access (Nikopour and Baligh 2013) and sparse index multiple access (Choi 2015). Thus, efficient ways to apply OFDM-IM to multiple access might be an important issue to be studied.

Space-frequency coding can be studied in the context of MIMO-OFDM-IM. A code word becomes a set of active indices in the space and frequency domains. Careful designs might be

required for codes of good energy and spectral efficiency.

There are also other directions as follows:

- Optical wireless: Optical OFDM is widely studied, and optical OFDM-IM is also studied (Baar and Panayrc 2015). Optical OFDM-IM can be investigated for Li-Fi that uses light for short-range very high-speed communications.
- Precoding and single-carrier systems: Precoding can improve the diversity gain at the cost of increasing receiver's complexity. Thus, through precoding, there might be a trade-off between performance and complexity, which is to be exploited to design a precoded OFDM-IM system with a given complexity constraint. If a precoding matrix is the Fourier transform matrix, the resulting OFDM-IM becomes single-carrier IM that can convey information by the set of active (i.e., non-zero) data symbols in the time domain. This can also be seen as a generalization of pulse-position modulation (PPM). Therefore, precoding can lead to a different level of generalization of IM in the time and frequency domains.
- Receiver design with imperfect channel state information (CSI): Imperfect CSI degrades the performance of receivers and results in an error floor in terms of bit error rate. In order to lower the error floor, low-complexity but near optimal receivers are required.

Definitions

The camera-based sensor receivers available on today's mobile devices prompt a new direction of research and applications, where visible light communication (VLC) can be combined with mobile computing to realize novel forms of sensing and communication applications. Optical camera communication (OCC) utilizes light-emitting diode (LED), LED arrays, or liquid-crystal display (LCD) as transmitters and employs camera-based sensors assembled in consumer electronic devices, such as smartphone and iPad as receivers to serve as an alternative to the photodiode (PD)- or avalanche photodiode (APD)-based receivers.

Historical Background

As a new emerging technology, VLC has great advantages over traditional radio frequency (RF)

communication in terms of communication security, environmental protection, and broadband high speed and is therefore increasingly attracting attention. In recent years, with the popularization of smartphones equipped with high-definition cameras and displays, a new technology called OCC has come into being. Utilizing the pervasive camera-based sensor as receivers, OCC provides a convenient communication mode interaction with the environment without additional hardware modifications (Pathak et al. 2015; Saha et al. 2015; Grobe et al. 2013; Wang et al. 2017; Haas et al. 2017).

It is well known that the camera-based sensor has a high resolution and can classify multiple spatially separated light sources. It is thus a natural multielement optical receiver. Meanwhile, it has a multicolor filter layout and easily separates the blended multicolor lights. Therefore, it is also a natural multicolor receiver. Moreover, a front optical lens can distinguish the light sources in the camera-based sensor and reduce the channel correlation. These appealing features make the image-sensor-based receiver suitable for imaging optical multiple-input multiple-output (MIMO) settings and are expected to support a huge number of parallel transmissions (Hranilovic and Kschischang 2006).

With these advantages of OCC, there are various potential applications, such as indoor localization (Liu and Pang 2003), intelligent transportation (Yamazato et al. 2014), screen-camera communication (Du et al. 2016), privacy protection (Hu et al. 2013), and unobtrusive communication (Yuan et al. 2012; Woo et al. 2012). Very high accuracy and ability to leverage the existing lighting infrastructure make OCC a good candidate for future indoor positioning applications. Meanwhile, VLC over a handset screen-camera link has become an attractive short-range wireless communication solution due to the high availability of camera-equipped smartphones over the past years, where information can be encoded as a stream of images and displayed in screens of smartphone, laptop, or advertisement boards. Besides, camera-based OCC approach is very attractive

for intelligent transportation, particularly on congested highways where the traffic density and the resulting contention impose challenges on traditional RF communications. Moreover, OCC supports unobtrusive communication imperceptible to human eyes between displays and cameras.

Despite various appealing features mentioned above, there are several factors that make OCC deployment challenging. The transmission speed of an OCC system is inherently limited by camera's frame rate. For most of commercial camera-based sensors, the frame rate is unstable and limited by the manufacturing process and image post-processing. And also the frame rate of commercial camera-based sensor is diverse. The frame rate mismatches between transmitter and camera receiver and thus results in mixed frames or lost frames. Consequently, the synchronization problem arises for the image-sensor-based receiver. Meanwhile, the shot noise in OCC originally modeled by Poisson statistics is signal-dependent. The signal-dependent noise model fundamentally requires complex modifications to signal processing and estimation/detection techniques to ensure optical data transmission and reception. Moreover, perspective distortions, misalignments, lens blur, and ambient light degrade the received signal quality and hence reduce information rate in OCC channels.

Foundations

Considering interference coordination and image reception as the main challenges in indoor OCC systems, the current network schemes will be first investigated. In what follows, for the point-to-point link-level system, modulation methods and synchronization algorithms will be discussed. Then, for the multiple-access-level system, several key issues including VLC cell layout, multiple-user access, and mobility management will be emphasized. Note that OCC emerges as a new form of VLC, thus within the levels of network and multiple-access in OCC systems, the slight differences between them are not to be described in the sequel.

Network Schemes

Indoor VLC technology possesses a broad spectrum, and light source deployments within a room can be dense and arbitrary. Hence, as a wireless communication network consisting of VLC, light fidelity (LiFi) (Haas et al. 2016) is an important means of complement conventional RF communications for improving area traffic capacity and dealing with high-traffic requirements.

VLC involves worse path loss and higher frequency than mm-wave communications do. The coverage of VLC cells may be reduced, leading to the concept of VLC attocells that are smaller than domestic microcells, femtocells, and wireless fidelity (WiFi). Hence, the network schemes of LiFi involve two types, i.e., pure light network (Sewaiwar et al. 2015b) and hybrid network (Jin et al. 2015). The downlink denotes the communication link from the optical transmitter to receiver, while the uplink denotes the backhaul link from the receiver to transmitter. Due to different backhaul infrastructures for uplinks, pure light network adopts VLC or invisible light such as a video streaming network with both infrared and visible light, whereas hybrid network is a combination of various technologies such as RF and free space optical links. Wang et al. (2013) presented a bi-directional VLC network, while red-green light is downlink and blue light is uplink. Li et al. (2015) discussed the resource allocation schemes based on different cooperative cell formations in a hybrid network.

Point-to-Point Link Level

In OCC system, the signals are modulated in intensity, color, or time-frequency domain for pervasive optical light sources (illumination LED, LED arrays, displays, or LCD). While the camera which consists of an imaging lens, a camera-based sensor, and a readout circuit, is used as receiver to detect the signals beyond traditional imaging. Generally, camera-based sensors can be classified into two categories, namely, charge-coupled device (CCD) camera-based sensor with global shutter and complementary metal oxide semiconductor (CMOS) camera-based sensor with rolling shutter. In a CCD camera-based sensor, the

global shutter exposes all pixels per frame simultaneously, while in a CMOS camera-based sensor, the rolling shutter exposes one row/column of pixels at a time and reads out the pixel voltages row by row or column by column. Due to excellent performance/cost trade-off, most personal mobile devices or high-end professional camcorders use CMOS camera-based sensors. Thus, only the CMOS camera-based sensors are discussed in the sequel.

Modulation Methods

Practically, an OCC system design requires consideration of human perception of light source flicker. Usually, the commercial camera's frame rate is lower than the transmission frequency. Thus, undersampling-based modulation methods are proposed to ensure no perceptual intensity fluctuation. Both undersampling frequency shift on-off keying (UFSOOK) (Roberts 2013) and undersampling phase shift on-off keying (UPSOOK) (Luo et al. 2014) modulation methods employ the undersampling technique to sample high-frequency signals and obtain the transmitter's states for data recovery. The UFSOOK is a form of direct current (DC) balanced differential coding, while the UPSOOK is similar to the phase shift keying (PSK), where the mark and space have the same frequency and amplitude, but the phases of the corresponding carrier signal are opposite. However, the spectral efficiencies are 0.5 bps and 1bps for UFSOOK and UPSOOK, respectively. In order to improve the spectral efficiency without increasing the number of transmitters, undersampling phase shift pulse amplitude modulation (UPSPAM) is proposed for high efficiency and non-flicking OCC (Luo et al. 2015).

As mentioned above, the CMOS camera-based sensor is a natural multicolor receiver enabled by a color filter array (Rajagopal et al. 2014), and thus color shift keying (CSK) modulation can be performed in OCC. With the ability of commodity cameras to detect a wide range of colors, it is possible to use high-order constellations with CSK (Hu et al. 2015).

It is known that a non-imaging optical MIMO system provides little diversity gain due to the

ill-conditioned channel matrix. However, optical lens can distinguish the source light images and reduce the channel correlation, which makes the imaging receiver one of the most efficient ways to apply optical MIMO. Specially, spatial orthogonal frequency division multiplexing (spatial OFDM) was proposed for imaging optical MIMO system, which encodes information in the spatial frequency domain. Due to the nonnegative requirement, the two-dimensional spatial DC-biased optical OFDM (SDCO-OFDM) (Katz and Bar-Ness 2015) and spatial asymmetrically clipped optical OFDM (SACO-OFDM) (Mondal et al. 2010) are proposed in an imaging optical MIMO system. Similar to one-dimensional optical OFDM, SDCO-OFDM uses a DC bias to convert the bipolar spatial OFDM signal into unipolar and thus suffers poor power efficiency. While the SACO-OFDM has been shown to be more efficient in terms of electrical as well as optical power, where only the odd spatial frequencies are used to carry data and the resultant bipolar signals are clipped at zero to generate a unipolar signal.

Note that generating the real-valued and positive signals imposes extra loss of at least 50% reduction in spectral efficiency. Moreover, the cyclic prefix further reduces the transmission spectral efficiency. Besides, the OFDM-based transmission has disadvantages of the high peak-to-average power ratio (PAPR) and high side lobe. Thus, WPDM has been proposed as an alternative for OFDM (Wong et al. 1997; Nikookar 2013). As one type of filter bank multicarrier (FBMC), WPDM employs orthogonal wavelet packet functions for symbol modulation. Similarly to OFDM, it provides orthogonality between subcarriers, while the basis functions are wavelet packet functions with finite length in time domain. And also in spatial WPSM system, the two-dimensional inverse discrete wavelet packet transform (IDWPT) and the two-dimensional DWPT are performed at the transmitter and receiver, respectively. The waveform bases for spatial OFDM methods are defined in the complex domain; however, the spatial WPDM bases can be defined either in the real domain or complex

domain, which is determined by the scaling and dilatation filters. Moreover, WPDM belongs to overlapped transformation, yielding better spectral concentration.

For the unobtrusive screen-camera communication systems, there are two kinds of modulation methods based on the space-time domain (Woo et al. 2012; Kays et al. 2017) and transform domain (Yuan et al. 2012; Kim et al. 2015), respectively. The space-time domain method primarily utilizes the equivalent low-pass characteristic and critical flicker frequency (CFF) of human vision. This method superposes information directly in time domain and leverages diversity and multiplexing in the spatial domain. The most common implementation of this method is complementary frame design. The transform domain method mainly exploits different sensitivity of human eyes to spatial frequency, superimposing information on the high-frequency component of spatial frequency to achieve the implicit effect.

Synchronization Algorithms

Although perfect synchronization is difficult in a practical OCC system, the imperfect frame synchronization issues must be addressed to achieve a high throughput. Except the oversampling approach, there exist some other algorithms to tackle the synchronization issue, such as per-line tracking and inter-frame coding (Hu et al. 2013) and rateless coding (Du et al. 2016). The per-line tracking and inter-frame coding synchronization algorithm adopts intra-frame per-line color tracking to decode the mixed frames. In what follows, it employs inter-frame erasure coding and frame-based tracking to recover lost frames and to prevent incorrect frames. Note that in this algorithm, all captured frames containing useful information can contribute to the overall frame recovery and result in reliable information transmission. While for rateless coding, it fits well with the channels in which interruptions occur frequently since the encoded bits of the same original information are generated continuously till the successful transmission is completed.

Especially for the unobtrusive screen-camera communication systems, the camera-based sensor might lose frames or capture mixed frame because of the temporal behaviors of displays and cameras (Shu and Wu 2016). The frame synchronization issues consisting of frame loss, frame fusion, and noise are taken into account in Li et al. (2017). The frame loss detecting algorithm is proposed based on the statistic characteristics of difference frames. Moreover, for the frame loss and frame fusion issues, a reasonable mathematical model is established, and robust frame synchronization compensation algorithms are proposed in Li et al. (2018b). At first, a frame loss detecting algorithm is proposed by analyzing spatial mean characteristic of difference frame absolute value. And then a detecting algorithm based on frame fusion fuzzy regions is proposed by utilizing row mean characteristic of difference frame absolute value and row variance characteristic of difference frame. To consider a configuration with low requirements for a camera where a display refresh rate is equal to the camera frame rate, a mixing factor representing a blend of adjacent frames is introduced in Li et al. (2018a). And also, based on the characteristics of the display-camera link and the simplified model under different imaging directions, a robust complementary frame design that can adapt to different imaging directions is derived.

Multiple-Access Level

VLC networks consider communication and illumination, leading to a key issue on cell deployments in the multiple-access level of indoor OCC systems. The links have directionality and vulnerability characteristics, owing to the straight propagation and common obstruction of visible light, respectively. Therefore, cell deployments in an OCC networking encounter several challenges related to these characteristics that differ from those of either WiFi or femtocell networks, such as illuminant cell layout design, multiple-user access, and mobility management.

Cell Layout

The VLC channel gain is influenced by the distance and illuminative orientation from

the light source to receiver. Deqiang et al. (2007) and Miya and Kajikawa (2010) studied both illuminance and received signal power distributions and determined an optimal base station layout. Chen et al. (2013) introduced the concept of multiple-point joint transmission (JT) into a VLC cellular network. Concurrent data transmission from multiple cooperating optical access point (AP) improved the cell-edge user signal quality. Due to the straight propagation of visible light, Rahaim and Little (2013) considered that it is flexible to adjust the coverage of VLC cells. Cell zooming method (Rahaim and Little 2013) was adapted for VLC to show coverage variability when transmitters are capable of dynamically changing their signal power, such that the requirements of both illumination and communication at cell edges are met.

Multiple-User Access

In VLC networks, the majority of multiple access schemes include two typical types, i.e., orthogonal multiple access (OMA) and non-orthogonal multiple access (NOMA). In OMA, it is typically realized by means of frequency, time, or code division. ACO-OFDM multiple access are usually adopted in VLC systems; however unipolar and real-time-domain OFDM signals are difficult to ensure compatibility with LED components (Bawazir et al. 2018).

Compared with OMA, NOMA can exploit the entire bandwidth for the time-frequency utilization of all degrees of freedom to increase spectral efficiency. The basic principle underlying NOMA is the superposition of signals in the power domain. Hence, more power is allocated to the farthest users in order to compensate for the user with poor-quality communication. Marshoud et al. (2015) developed a framework based on VLC channel gain ratio for a downlink NOMA power allocation scheme in an indoor multiple-LED VLC system. Yin et al. (2016) analyzed the performance of outage and capacity in NOMA-VLC networks and discussed the relationship between illuminative angles and VLC network throughput. To discuss the user data rate of NOMA based on indoor VLC channels, Tao et al. (2018) presented an alternative lower bound

to asymptotically fit the system throughput of NOMA-VLC.

Mobility Management

The light radiation pattern of a visible light source with strong directionality confines the coverage area of VLC AP, leading to the inflexible mobility and handover limitation. Due to these actual use demands, mobility management is commonly studied in hybrid RF and VLC networks. Sewaiwar et al. (2015a) proposed a mobility support scheme based on color clusters and the mobility support is efficiently provided using a color filter array at receivers. Wang et al. (2016) presented a hybrid network handover scheme based on fuzzy logic, considering the quality of service (QoS) requirements and indoor mobility of VLC users.

Key Applications

In 2007, visible light communications consortium (VLCC) of Japan presented the VLC system standards JEITA CP-1221 and JEITA CP-1222 (Ergul et al. 2015), including the specification of subcarrier bandwidths. In 2008, infrared data association (IrDA) and VLCC proposed physical layer technical requirements, combining infrared data with VLC (Ito and Matsumoto 2009). In 2010, the European Union performed a home gigabit access (OMEGA) project, which investigated the use of VLC in wireless communication (Langer et al. 2008). In 2011, the Institute of Electrical and Electronics Engineers (IEEE) Standards working groups set the 802.15.7 specification of physical layer and medium access control (MAC) (Roberts et al. 2011; Bawazir et al. 2018). As a revision of IEEE 802.15.7 VLC standard, IEEE 802.15.7r1 incorporates new physical layers to support OCC functionalities and MAC modifications (IEEE-802.15-WPANTM 2018). In 2016, the Chinese Wireless Personal Area Network (CW PAN) published the white paper of VLC standards (CESI 2016), involving mobility management and interference mitigation.

Industrial Big Data

Lin Gu

SCTS, CGCL, School of Computer Science and Technology, Huazhong University of Science and Technology, Wuhan, China

Definition

Industrial big data refers to the large amount of data generated by various industrial equipments in production and marketing process. The industrial big data is more orderly, structured, timely correlated and therefore more ready for intelligent analytics to support decision making,

reduce maintenance cost and improve customer experience.

Historical Background

The concept of industrial big data is proposed along with the strategies of the “Industry 4.0” of Germany” in 2012. With the development of “Industrial Internet” in US, the “Manufacturing White Book of 2014” in Japan, and the “Made in China 2025” and “Internet plus” in China, big data based intelligent manufacturing has attracted an ever-growing attention of industrial enterprises and industry related communities globally.

Industrial Big Data Life Cycle

A typical industrial big data life cycle usually consists of the following four parts:

- **Data Generation**

Industrial big data is usually generated by diverse sources in manufacturing spaces and production process, mainly including the following: (1) device data, data generated by the physical devices such as actuators, sensors, and cameras; (2) production data, data generated during the production process, including product design and manufacturing, quality testing, and device maintenance; (3) operation data, data related to the enterprise operation, e.g., enterprise organization, business management, marketing, quality control, and e-commerce plan; and (4) manufacturing chain data: data related to customers, suppliers, business partners, and so on

- **Data Acquisition**

With the development of intelligent manufacturing, the industrial data and manufacturing devices are rapidly growing in both quantity and complexity, requiring industrial data acquisition in real time. Two key technologies as data fusion and data integration are usually applied to synthesize industrial data from

different sources to find their interlink and provide users with a unified view, producing more useful and meaningful information for further analytics and queries.

- **Data Storage**

To manage massive heterogeneous industrial data and enable real-time analytics, the data storage system should be designed for high capacity, low latency, rapid access, and fault tolerance. Big data storage supports storage and I/O operation of massive files and provides basic distributed database functionalities. The storage infrastructure is usually made up of direct attached storage and network attached storage, enabling fast access and retrieval of large amount of data. Typical big data storage architecture/infrastructure solutions include Hadoop, Cassandra, NoSQL, and so on.

- **Data Analytics**

Industrial data analytics is considered as a useful tool to understand customer demands, market trends, and device maintenance, helping to make future plans for industrial enterprises. Due to the large quantity and complex structure of big data, industrial data analytics should be able to provide multi-view understanding of massive data from diverse sources and discover valuable information. Some key technologies include association rule learning, classification tree analysis, genetic algorithms, machine learning, regression analysis, and sentiment analysis.

Enabling Technologies

Modern smart industry can be viewed as a manufacturing cyber-physical system (CPS) consists of both physical devices such as machines, sensors, and information systems to collect, process, and store data produced by these devices. Industrial big data leverages various information technologies such as wireless communications, edge computing, and machine learning for supply chain improvement, device health monitoring, and customer relation management toward low-cost, efficient, and sustainable industry. Many

related enabling technologies have been proposed and applied to the four phases of industrial big data life cycle.

- **Wireless Communications**

Industrial big data are usually acquired via wireless communication from both industrial devices (e.g., machine temperature and vibration) and production procedure (e.g., raw material supply and product quality). Previous wireless communication standards such as LTE-A, WiMax, UMTS, and LTE are usually designed to achieve high throughput and high reliability. However, with the ever-growing sensors and devices involved in the smart factory, it is widely agreed that 5G technology (Palattella et al. 2016) which supports vast device connectivity with higher data rate, higher system capacity, and lower energy consumption should be applied toward high efficient data transmission and massive connections.

- **Edge Computing**

Edge computing offers an ideal platform to offload applications, data, and services from central cloud to local information devices such as servers and base stations (Shi et al. 2016). It enables data processing, analytics, and knowledge generation near the data source with lower latency and higher efficiency. Such advantages fit the needs of smart industry that requires fast data processing and prompt response. For example, one of the key issues in smart industry is machine failure prediction. A large volume of sensing data should be processed in a real-time way, and immediate decision or predictions should be made for the production procedure. In this case, cloud computing is no longer desired with the consideration of high communication cost and latency, while processing the data at edge nodes without data transmission becomes a promising solution.

- **Machine Learning**

Machine learning algorithms and models have been developed for several decades to effectively perform specific tasks without using

explicit instructions or fixed rules. Many different machine learning technologies with different capabilities have been proposed, e.g., decision tree, support vector machine, deep neural network, and reinforcement learning, to perform pattern recognition, trend prediction, and dynamic control (Lei et al. 2016). The industrial big data is usually ordered, structured, timely correlated and therefore ready for further analytics to support smart manufacture. By leveraging machine learning algorithms, enterprises can make the messy industrial data into valuable information, build a knowledge base of the production procedure, and make predictions or decisions automatically.

Key Applications

Through intelligent analytics of large amount of industrial data generated from diverse sources, we can significantly improve industry related management, including marketing decisions and future enterprise resource allocation. Some key applications are listed as follows:

- **Supply Chain Improvement**

Industrial data analytics helps us to predict the future of manufacturing. Thanks to new cloud data management tools and increasing supply chain software platforms, real-time supply chain analytics has become a trend. Specially, enterprise managers now can better understand changing marketing trends and identify investigate risks and thus update supply chain strategies and manage supply chain operations (Wang et al. 2016). For example, data analytics results can be applied to supply network and logistics function design, improve supply chain operations, measure supply chain performance, reduce supply variability, and implement better supply chain strategies at the tactical and operational level.

- **Customer Relation Management**

With the growing of global industrial markets, enterprises are keen to integrate customer-

related data into manufacturing processes with the goal of improving customer satisfaction, calculating investment return on initiatives, and predicting customer behavior (Alqahtani and Saba 2013). The product selling records tell if the sales strategies should be adjusted in one particular area, e.g., keeping low prices or changing advertising plans. Keeping track of the consumers' feedback data or product reviews allows enterprises stay in touch with customers even after the deal. Such data can be analyzed and quantified to help the enterprises to know better about their customers and incorporate necessary changes on the products for better customer experience.

- **Machine Health Monitoring**

The machine condition data and related analytics algorithms to calculate machine health and performance behavior can effectively protect hardware assets and reduce manufacturing downtime (Xu et al. 2015). In modern industrial factories, machine health monitoring is considered as an efficient method to reduce downtime and preserve assets. Usually, some fixed sensors are involved in order to collect data of machine working conditions, e.g., temperature, noise, and vibration frequency. The sensing data could be used for real-time analysis on different machine performance evaluation and future maintenance scheduling.

- **Decision-Making Support**

The main objective of manufacturing decision is to achieve effective and efficient production. The rich production data can be used to assist the decision-making in production control to achieve high reliability and availability (Lee et al. 2014). For example, by analyzing the production data, useful knowledge can be derived to reduce production uncertainties and utilize finite resources on bottleneck sections of manufacturing system, aiming to efficiently reduce the unexpected downtime and machine failures.

With a real-time data management platform, the data from different industrial sources can be

used to provide big data predictive analytics, improve the flexibility of manufacturing pipelines, and maximize the utilization of enterprise resources.

Definition

Information-centric networking (ICN) is an approach for communication in a network that provides accessing named data objects as a first order service.

Historical Background

According to the Cisco Visual Networking Index (VNI) report (Cisco visual networking index: forecast and methodology: 2015–2020 [2014](#)), global IP traffic will reach 194 exabytes per month or 2.3 zettabytes per year by 2021. The content retrieval applications are the most of the traffic, such as delivering multimedia content (e.g., Netflix) and sharing user generated data (e.g., YouTube) (Borst et al. [2010](#)). The widespread Internet multimedia traffic will be 82% of global consumer Internet traffic in 2021. The various of video (e.g., TV, VoD, Internet, and P2P) will be roughly 86% of all global IP traffic (Intel [2016](#)). In the current Internet for applications, some distribution services and technologies are used to address the issue of increasing traffic volume by employing content distribution, replication, and caching in different ways. Hence, P2P networking and CDNs are employed, which are implemented typically as an overlay. Moreover,

the distribution approaches access by name, regardless of origin server location. However, scalable content distribution and information sharing cannot be supported adequately via the current Internet, which is centered on the host-to-host communication model. For this reason, the networking community is proposing novel Internet architectures and paradigms to rectify the drawbacks of the current Internet. Information-centric networking (ICN) is a promising Internet architecture in satisfying the requirements of the future networks. The history of ICN can be dated back to the work of Cheriton and Gritter, who introduce a name-based routing in TRAIID (Cheriton and Gritter [2000a, b](#)). Then, Data-Oriented Network Architecture (DONA) was proposed in 2007 (Koponen et al. [2007](#)), which is the first clean-slate ICN architecture. Subsequently, ICN has attracted researcher interests of many networking communities. In order to investigate ICN, many projects have been funded, including Content Centric Networking (CCN) project, Named Data Networking (NDN) project, [MobilityFirst project](#), [ICE-AR project](#), Publish-Subscribe Internet Technology ([PURSUIT](#)) project, Scalable & Adaptive Internet soLutions ([SAIL](#)), COntent Mediator architecture for content-aware nETworks ([COMET](#)), [CONVERGENCE](#), [ANR Connect project](#), [GreenICN project](#), and [ICN-2020 project](#).

Foundations

ICN is different from the current Internet, which uses IP addresses to transfer data packets. Moreover, ICN does not care the locations of the contents by assigning contents names. In ICN, each data is assigned a name. In addition, users consume contents by sending requests including content names to the network, which then routes the requests to nearby copies of the desired contents by using the content names. Therefore, names play a key role in forwarding decisions and are used to match requests. Moreover, each ICN node is enabled to cache contents and perform forwarding decisions on a path. Ubiquitous

in-network caching can enable sharing and be used to make communication more robust. In addition, transport protocols of ICN are based on a receiver-driver model, i.e., by regulating the request sending rates, message sending rates are controlled by requestors. ICN can achieve retransmission by resending requests. Hence, ICN is a receiver-driven communication model. Compared with the current Internet, the content is decoupled from its location in ICN. Thus, the IP address be replaced by the content name. For example, CCN uses named content chunks to replace the current narrow waist of IP; see Fig. 1. Moreover, ICN users are only interested in what the content is, but do not care where the content comes from.

Next, we describe the ICN forwarding engine, which is shown in Fig. 2. CS is used to cache data, the return path state is stored in the PIT, and probable source(s) for data can be stored in FIB. The routing nodes in the network receive the interest packet when users send a request to the network. Moreover, the routing node looks up its own CS. If CS contains the object, then the content object is sent to the requestor. If CS does not find the object, then the node looks up its own PIT. If no object found, then forward the request toward the data source according to the routing mechanism. In addition, some key functionalities are presented as follows.

- **Naming:** The naming of content is one of the main characteristics of each ICN architectural proposal. For individual content, unique name is required. In all ICN architectures, content names are used to identify contents independently of their locations. In addition, naming schemes are divided into two types: flat and hierarchical namespaces. For example, the hierarchical naming scheme is used to improve routing scalability in Content Centric Networking (CCN). While NetInf uses the flat naming scheme.
- **Security:** The security of ICN is closely related to the naming in several ICN architectures. The current Internet uses encryption and authentication to ensure security. Different from the current Internet, security cannot be bound to the storage location since ICN users can obtain the requested content from multiple sources. In order to verify the integrity of the named content, a security mechanism at receivers is provided by ICN. Moreover, content authentication, access control and authorization, encryption, traffic aggregation and filtering, state overloading, delivering content from replicas, cryptographic robustness, and routing and forwarding information bases are important security features in ICN.
- **Routing and name resolution:** ICN routing constructs a path for finding a named content based on its name, which is provided initially

**Information-Centric
Networking: Basic
Principle
and Architecture, Fig. 1**
The CCN architecture

Information-Centric Networking: Basic Principle and Architecture, Fig. 2 The ICN forwarding engine

- by a requestor. ICN routing is divided into three steps. Firstly, the name of the requested named content is translated to its location by the name resolution step. Secondly, based on its name or location, the request is routed to the content by the discovery step. Finally, the content object is routed to the requestor by the delivery step.
- **Mobility:** ICN natively supports the mobility of the subscriber, since mobile subscribers use content name to request content and the content is transported from publishers to subscribers by a connectionless manner in ICN. Unlike subscriber mobility, publisher mobility support is more difficult, since content identifier and routing locator cannot be separated.
 - **Caching:** Any ICN element is enabled to cache named content, such as end-user devices, proxy caches, and routers. The network utilization and data availability can be improved by content caching, since the content is fetched from nodes that are closer to the requestor in geographical location. Caching approaches can be divided into in-network caching and caching at the network

edge. For in-network caching, the content is cached in the transport network. In general, in-network caching can be divided into off-path and on-path caching. Caching at the network edge means that the content is cached at the edge nodes such as replicated servers.

- **Rate and Congest Control:** Since ICN is a receiver-driver communication model, a requested content can be obtained from multiple sources. Thus, the requestor can control the data rate by regulating the sending rate of its request.

The functionalities above need be considered in all the ICN architectures but rather in the specific ICN architectures.

Key Applications

ICN can be applied to many areas, such as web applications, video streaming and download, and Internet of Things (IoT). The aim is to provide benefits for application developers by employing the advantages of ICN.

Future Directions

From the evolution of ICN, there are some research challenges, including naming schemes for ICN, scalable routing schemes, congestion control, QoS approaches, caching strategies, Metrics for evaluating implementations of ICN, security and privacy, application-protocol design, business, legal and regulatory frameworks, etc.

[Content-centric wireless sensor networks](#);
[Data-centric wireless sensor networks](#);
[Data-oriented wireless sensor networks](#)

Definitions

An information-centric wireless sensor network is an information-centric network (ICN)-enabled wireless sensor network, where network users aim at requesting and delivering information instead of establishing end-to-end or point-to-point sensor connections and data communication.

Historical Background

A wireless sensor network (WSN) (Akyildiz et al. 2002) is a system containing sensors and related network components for external environment monitoring, information collecting, and transmission, e.g., military surveillance, area detection, and healthcare monitoring. Conventionally, multiple dedicated sensors (e.g., air pollution sensors and temperature sensors) are deployed in physical environments by the sensor owners. A centralized gateway device can be set up for gathering collected data for further process by WSN information and service users. Sensed data need to be merged and routed to corresponding

gateway devices by employing various data delivery algorithms (Al-Karaki and Kamal 2004).

As WSN systems usually provide underlying information delivery services for smart and social applications, it is critical to ensure the quality of information flows within the WSN systems. However, comparing with other popular types of wireless networks, such as mobile ad hoc networks and cellular networks, a WSN system usually involves a large amount of wireless sensor nodes (e.g., over 100 nodes in each 25 m² area (Selavo et al. 2007)), which results in high complexity of network topology as well as end-to-end network node connections. Large overhead of communications may occur when traditional heavyweight networking protocols and communication schemes are applied to WSN systems, e.g., TCP/IP. Additionally, several issues related to information in WSNs are also critical to the applications users of WSNs, e.g., information timeliness, information quality, and fault tolerance/correction issues. To this end, WSN systems need to be viewed and analyzed from a complete different network paradigm perspective.

The concept of information-centric network (Ghodsi et al. 2011) can be applied to WSN systems which mainly focus on efficient data delivery and information service quality, namely, information-centric WSN (Xu et al. 2014; Singh and Al-Turjman 2016; Chen et al. 2016; Al-Turjman 2017). Instead of employing network address based on end-to-end communications (e.g., IP address), an information-centric WSN allows network components to request for information based on the “name” of information. That is, a sensor node sends a request for a particular type of information to the network without being aware of the exact location of the information and the routing details. In a similar manner, a network component who has the information requested by other users only responds to the arriving requests of the information, without establishing an end-to-end route to the request source. Maintaining routing paths for information delivery at the information owner and requester sides is not necessarily required. By this means, information

in the WSN systems is decoupled from physical sources and locations. The delivery processes are implemented by any means of the network itself. Information generation and delivery in WSN systems can be more scalable.

At present, WSN systems have been developed and extended to new scenarios and concepts, e.g., Internet of Things (IoT), which involves smarter sensor devices, as well as cognitive and social network users, including human user network nodes. Social and human factors and behaviors involving information flows, as well as information value and network user incentives in such systems, are extensively studied recently (Mainetti et al. 2011; Gubbi et al. 2013). In this case, Information-centric WSN system architecture can provide an intuitive framework for such studies.

Foundations

System Components and Architecture

A conceptual reference architecture for information-centric WSN systems is shown in Fig. 1, which mainly consists of three layers of different functionalities.

- **Layer I, information sensing and generating layer:** WSN nodes, working in this layer sense, collect and generate raw data either from the environment, e.g., temperature data and video files.
- **Layer II, information processing and networking layer:** Raw data from Layer I is processed and physically delivered in this layer and used to provide services. The services can be formed as structured and interpreted information bundles by selectively combining and employing the raw data passed to this layer, e.g., using machine learning algorithms.
- **Layer III, information application layer:** Information services in this layer are applied to serve the needs and demand of WSN users. WSN users may initiate their requests for different types of information or respond the requests for the information owned.

The information-centric architecture for WSNs allows cross-layer implementations. The key idea is to consider information flows rather than device placements as in conventional WSN systems. This information-centric architecture promotes cross-layer designs and implementations. As many sensor devices have more computing capability nowadays, e.g., smartphones, primitive functions can be provided locally by each device (or a group of devices) to meet immediate information requirements of WSN information and service users. For example, noise can be removed from the sensed information by sophisticated algorithms running by the smartphones. In this regard, sensing devices defined as micro providers (Bohli et al. 2009) can operate across Layers I and II of the ICN architecture as in Fig. 1.

Value of Information

As modern WSN systems involve human and social participants, in information-centric WSN systems, information flow can be valued with the *value of information*. Applying information-centric architecture is intuitive in market-oriented modeling and analysis for information trading in WSN systems. With the architecture, WSN system components can concentrate on the content and timeliness while acquiring data from the system, instead of low-level communication issues. In this case, information is treated as commodities, and information transfer is considered to be market transactions. Additionally, sensing behaviors are considered as services provided by wireless sensor nodes. Activities to handle and process the collected information can be seen as value-adding or value generation processes. Consequently, information becomes expensive in value when the scale of data sensing, collection, and processing and the complexity of WSN applications increase. Therefore, transfers of raw data and processed information should involve value interpretation/proposition and reward implication in terms of either monetary or other types of incentive as in market trading.

Value of information needs to be revealed to WSN system components by means of market-oriented approaches and pricing schemes, such as smart data pricing (Sen et al. 2015), where

WSN system resource including information and services can be dynamically priced. For example, auction is a classical market-oriented method for valuating and allocating exclusive resources among multiple users. Rational WSN components may negotiate and quote their ask and bid prices for the resources. A practical scenario is a mobile crowdsensing scheme in smart cities (Pouryazdan et al. 2016), where an application task runs a reverse auction to select smartphones (as WSN components) for data sensing and collection. By trading information, market efficiency and social welfare maximization can be achieved.

Sensing as a Service

A set of information trading business frameworks has been categorized into Sensing-as-a-Service (S2aaS) (Charith et al. 2013; Guijarro et al. 2017). WSN nodes perform four types of conceptual tasks in WSN systems (Charith et al. 2013), including data collection, data publishing and transfer, data processing, and data application. A WSN system can be viewed as a WSN market in the S2aaS framework, where information can be circulated as a service-type commodity, and priced based on their market values in the trading processes in terms of their different service qualities.

Age of Information

Age of Information (AoI) (Kosta et al. 2017) can be imported as a concept to measure the quality of information flows in WSN systems in terms of freshness, which is defined as the time interval from the most recent update of the information at the information recipient side. Network users may operate as “free riders” that wait until free or low-priced information is disseminated across the WSN network as time elapses. However, as AoI increases with time, the trading value of information decreases immediately after the information is generated. Discriminatory pricing strategies, i.e., based on the time that the information is made available to a network component, can be adopted. As such, the users should have urgent intent to “buy” information before the information becomes not fresh or even obsolete.

Information-Centric Wireless Sensor Networks, Fig. 1 Conceptual architecture for information-centric wireless sensor networks

Key Applications

Information-centric wireless sensor network paradigms enable the designs and deployments of cognitive and intelligent WSN systems, where

system components mainly value and focus on data requests and data deliveries, instead of end-to-end transmissions. Availability, quality, and valuations of data delivered are important metrics in information-centric wireless sensor networks.

Definition

Integrated systems of networking, caching, and computing refer to integrated frameworks and technologies in wireless or mobile communication systems that take into consideration at least two aspects of networking, caching, and computing, aiming at providing coherent and sustainable services to fulfill various mobile network user demands, such as high-data-rate communication, low-latency information retrieval, and extensive computation resources.

Historical Background

Software-Defined Networking (SDN), Network Functions Virtualization (NFV) (Liang and Yu 2014), and Heterogeneous Network (HetNet) are key supporting technologies from the networking vector of the integrated system. SDN can enable the separation between the data plane and

the control plane, therefore realizing the independence of the data plane capacity from the control plane resource, which means high data rates can be achieved without incurring overhead on the control plane. Meanwhile, the separation of the data and control planes confers high programmability, low-complexity management, convenient configuration, and easy troubleshooting on the network. NFV presents the technology that decouples the services from the network infrastructures that provide them, therefore maximizing the utilization of network infrastructure by offering the possibility that services from different service providers can share the same network infrastructure (Liang and Yu 2015). Furthermore, easy migration of new technology in conjunction with legacy technologies in the same network can be realized by isolating part of the network infrastructure (Liang and Yu 2014). On the other hand, HetNet has the potential to considerably improve network coverage and link capacity (Xie et al. 2012). By employing different sizes of small cells and various radio access technologies in one macro cell, energy efficiency (EE) and spectral efficiency (SE) are significantly enhanced in scenarios such as shopping malls, stadiums, and subway stations (Ma et al. 2004; Yu and Krishnamurthy 2007).

The early stage of caching technology in wireless communication system includes Content Delivery Networks (CDNs) and Peer-to-Peer (P2P) networks, which are proposed as first attempts to confer content distribution and retrieval capabilities on the networks by utilizing the current storage and processing network infrastructure (He et al. 2017b). CDNs employ clusters of servers among the Internet infrastructures and serve the user equipment (UE) with the replications of content that have been cached in those servers. The content requests generated by UE are transmitted through the domain name servers (DNSs) of the CDN to the nearest CDN servers that hold the requested content, in order to minimize latency. P2P networks rely on the storage and forwarding of replications of content by UE. Each piece of UE can act as a caching server in P2P networks. In P2P networks, the sources of content are called

peers. Instead of caching a complete content, each peer may store only a part of the content, which is called a *chunk*. Thus, the content request of a piece of UE is resolved and directed to several peers by a directory server. Each peer will provide a part of the requested content upon receipt of the request. Serving as an alternative to CDN and P2P networking, *Information-Centric Networking (ICN)* emphasizes information dissemination and content retrieval by operating a common protocol in a network layer, which can utilize current storage and processing network infrastructures to cache content.

Powered by network slicing, SDN (He et al. 2017a), and NFV, Cloud Computing (CC) functionalities are incorporated into mobile communication systems, bringing up the concept of *Mobile Cloud Computing (MCC)*, which leverages the rich computation resources in the cloud for user computation task execution, by enabling computation offloading through wireless cellular networks. After computation offloading, the cloud server will create a clone for each piece of UE individually, and then the computation task of the UE will be performed by the clone on behalf of that UE. Nevertheless, due to the fact that the cloud is usually distant from mobile devices, the low-latency requirements of some latency-sensitive (real-time) applications may not be fulfilled by cloud computing (Wang et al. 2018). Moreover, migration of a large amount of computation tasks over a long distance is sometimes infeasible and uneconomical. To tackle this issue, *fog computing* has been proposed to provide UE with proximity to resourceful computation servers. It is a distributed computing paradigm in which network entities with different computation and storage abilities and various hierarchical levels are placed within a short distance from the cellular wireless access network, connecting user devices to the cloud or Internet. A new MCC paradigm similar to fog computing, named *Mobile Edge Computing (MEC)*, is proposed. Being placed at the edge of radio access networks, MEC servers can provide sufficient computation resources in physical proximity to UE, which guarantees the fulfilment of the demand of fast interactive response by low-latency connections (Wang et al. 2017a,b).

Key Points

Caching-Networking

The multilayer caching-networking framework is illustrated in Fig. 1; this framework consists of the following five cached content delivery approaches.

- Device-to-Device (D2D) delivery (Fig. 1a)
Content requested by UE can be retrieved through D2D links from neighboring UE. A high density of UE can contribute to a high probability of successful retrieval of requested content.
- Multihop delivery via D2D relay (Fig. 1b)
D2D communication links can serve as a relay for content delivery from other sources to the destination UE. This approach enables a broader range of caching and delivery.
- Cooperative D2D delivery (Fig. 1c)
If multiple UE hold the content requested by another UE, they can cooperatively transmit the content to the destination UE through a D2D multiple-input multiple-output (MIMO) technology to accelerate the transmission process.
- Direct small cell base station (SBS) delivery (Fig. 1d)
If the requested content was cached in the associated SBS, the SBS can transmit it directly to the destination UE.
- Cooperative SBS delivery (Fig. 1e)
If the content requested by certain UE was stored neither in its nearby UE nor in its associated SBS, it may retrieve and demand the content from an SBS in a neighboring small cell. In this case, the associated SBS will require the demanded content from neighboring SBSs through virtual links, which means these two SBSs are able to communicate with each other via their respective backhauled to the macro cell base station (MBS).

Computing-Networking

Cloud Mobile Media (CMM) is a typical computing-networking approach and is hence used to illustrate the structure of this type of integrated systems. The overall architecture of CMM is depicted in Fig. 2 (Wang and Dey 2013).

Integrated System of Networking, Caching, and Computing, Fig. 1 Networking-caching framework (Sheng et al. 2016)

Integrated System of Networking, Caching, and Computing, Fig. 2 Cloud mobile media framework, demonstrating data and control flows (Wang and Dey 2013)

Integrated System of Networking, Caching, and Computing, Fig. 3 Caching-computing architecture (Zeydan et al. 2016)

The control commands are transmitted uplink via cellular radio access networks (RAN) to gateways located in core networks (CN) and eventually to the serving clouds. After that, the clouds perform data processing or content retrieval using computing or caching resources in cloud servers, in accordance with user control commands. Then the results are sent back to user devices downlink through CN and RAN.

Caching-Computing

In the context of big data, which has attracted great attention in recent years, data management/processing and data caching have emerged as two key issues in this field. The study of Zeydan et al. (2016) proposes a caching-computing framework in which cached content is moved from the cloud to the RAN edge and a big data platform powered by machine learning and big data analytics is deployed in core site for content selection. As illustrated in Fig. 3, the caching platform at small cell base stations (SBSs) and the computation and execution of the content prediction algorithms at the core site are two key components of the proposed architecture. A big data platform is employed at the core site to perform tracking and prediction of users' demands and behavior for content selection decisions, and SBSs in the RAN are equipped with caching units to store the strategic content selected by the big data platform.

Caching-Computing-Networking

1. Networking-Caching-Computing Convergence

The study in Huo et al. (2016) proposes a framework incorporating networking,

caching, and computing functionalities under the control and management of an SDN control plane. A software-defined approach is employed in the integrated framework, in order to leverage the separation of the control plane and the data plane in SDN, which helps guarantee flexibility of the solution.

2. Networking- and Computing-Assisted Caching

The study in Khan and Ghamri-Doudane (2016) proposes a socially aware vehicular information-centric networking model, in which mobile nodes such as vehicles are equipped with communication, caching, and computing capabilities and they are responsible for computing their eligibility for caching and delivering content to other nodes (i.e., the relative importance of vehicles in the network, with respect to user interests, spatial-temporal availability, and neighborhood connectivity).

Key Applications

Integrated System of Networking, Caching, and Computing is essential in any environment where multiple types of service are requested.

Intelligence and Trading with Energy Storage and Renewable Generation of Microgrids

Hongseok Kim

Department of Electronic Engineering, Sogang University, Seoul, South Korea

Synonyms

[Peer-to-peer energy trading of microgrids](#)

Definitions

A microgrid is a power system having at least one distributed energy resource to serve its internal load (Kim 2011). It performs an intentional island operation upon a power disturbance in the electrical distribution network. However, in a normal mode of operation, microgrids are connected to the main grid and can import/export power from/to the power grid or other microgrids.

Historical Background

To set out an agreement for greenhouse gas emission reduction, 195 countries participated in the 2015 United Nations climate change conference (also known as COP 21 or CMP 11) in Paris and established, by consensus, the goal of limiting global warming by below 2 °C. Since the energy sector accounts for roughly two-thirds of greenhouse gas emission, these countries might not effectively combat against climate change without fundamentally shifting

the way of producing energy (e.g., electricity). New York State has recently implemented its Reforming the Energy Vision strategy to create a greener, more resilient, and affordable energy system by utilizing renewable energy sources in community-based microgrids. In the UK, 10 million households are expected to have solar panels on their roofs by 2020 and will be more likely to reformulate electricity market structures as prosumers, that is, both producers and consumers. Although renewable energy can contribute to reducing overall energy costs and carbon emission, its inherent volatility still remains to be resolved as the penetration level of renewable generation continues to increase.

Hence, for reliable operation, microgrids are required to forecast electric loads and renewable generations with reasonable accuracy by utilizing the state-of-the-art forecasting technologies based on machine learning and artificial intelligence. Once determining energy surplus and/or deficit in each hour of operation, microgrids can participate in energy markets, either the existing wholesale electricity market, or the upcoming peer-to-peer (P2P) energy trading market. The focus of this entry is on the emerging P2P energy market.

Electric Load Forecasting

Microgrids first need to forecast their electric loads for reliable operation and energy trading. Thus, electric load forecasting, or simply called load forecasting, is one of the main research areas in the smart grid and can be classified depending on its target forecasting ranges from minutes to years (Ryu et al. 2016). Among these, short-term load forecasting (STLF), which focuses on predicting the load of hours or days ahead, secures attention in the smart grid because of its wide applicability to demand side management, energy storage operation, peak load reduction, etc.

So far, load forecasting is vitally important for the electricity industry in the deregulated electricity market. Furthermore, accurate models for electric load forecasting are also essential for the operation and planning of a utility company.

In addition, demand response is considered as one of the least expensive resources available for operating the system according to the new paradigm under deregulation, and thus, load forecasting is important. Accurate demand forecasting can encourage customers to participate in demand response programs and to receive monetary rewards from the utility company. Meanwhile, in the deregulated retail market, various end-user services, such as customer load management, require load forecasting to attract more customers. These characteristics imply that the role of consumers would be more significant than before, and thus, the scope of forecasting is shifted from the macroscopic view to the microscopic view including the microgrid level.

There are many research activities on forecasting models from classical time series analysis to recent machine learning approaches. Time series analysis, one of the most popular load forecasting methods, includes the autoregressive integrated moving average (ARIMA), exponential smoothing, and the Kalman filter. A double seasonal Holt-Winters model (exponential smoothing) is also popular with better results than ARIMA. Another branch of load forecasting is to use an artificial neural network (ANN) mode. Since ANN can model nonlinearity, it is widely used for various forecasting applications. It is known that network structure plays an important role in ANN because feature information about the model, including the forecasting period or what variables are used, is reflected in the structure of neural networks. The most common type of ANNs is a multilayer perceptron (MLP) that forecasts a load profile using previous load data.

A deep neural network (DNN) is an ANN with more layers than the typical three layers of MLP. The deep structure increases the feature abstraction capability of neural networks. Recent progress of the Internet of Things (IoT) and big data enables the adoption of DNNs in diverse research fields such as computer vision, natural language, signal processing, and deep learning methods are being applied to the domain of load forecasting. Since electricity load is time series data, research studies have been mainly conducted on deep neural network (DNN), recur-

rent neural network (RNN), and long short-term memory (LSTM). DNN is utilized by two different ways (Ryu et al. 2016): one is with pretraining restricted Boltzmann machine and the other is with using rectified linear unit (ReLU) without pretraining. Feed-forward deep neural network and recurrent deep neural network such as LSTM are also possibly combined. Convolutional neural network (CNN) can be also used for load forecasting, and it shows good performance because CNN is good at extracting the features of input data and captures daily, weekly, or seasonal periodicity.

Renewable Energy Forecasting

In addition to load forecasting, renewable energy requires advanced forecasting technologies. Recently, various renewable energy sources such as solar and wind are integrated into the power grid. However, solar power outputs heavily depend on weather conditions such as clouds, temperature, and humidity. This causes substantial uncertainties, which brings adverse effects on economic benefit and the stability of the power grid. Thus, accurate solar forecasting techniques are required to balance the power grid and/or microgrids.

The nonstationary characteristics of solar irradiance mainly come from the presence of clouds because of their stochastic blocking of sun light. This causes the system hard to predict the solar power output. Cloud motion vector can be used for higher accuracy using sky observing cameras, e.g., sky imagers. However, these cameras are usually expensive to be deployed with solar panels, and they are only capable of learning in a very short-term horizon, i.e., less than an hour. Satellite images can be used for generating the solar irradiance forecasting in hourly horizons. However, wide-area satellite images are not suitable for capturing the site-specific information for microgrids. Recent studies have mainly used machine learning approaches to predict multisite solar power output by hourly horizons. There are many time series prediction schemes to extract the relations on historical global (or multisite)

horizontal solar irradiance data and the future solar power output. In general, linear autoregressive prediction models have been used, but nonlinear methods outperform the linear techniques for forecasting horizons more than an hour.

For nonlinear time series prediction, support vector regression (SVR) and ANN are usually used. They are adequate for short-term horizons, i.e., up to 6 h. The numerical weather prediction-based forecasting models are more accurate for long-term horizons more than 6 h. Several studies use forecasted meteorological parameters to improve forecasting accuracy for the short-term forecasting horizons. This meteorological data should be collected by the close weather forecasting station to consider site-specific conditions in a target area. For example, the forecasting accuracy can be improved for 1 h ahead forecasting by using forecasted meteorological data such as clouds, humidity, and temperature. However, this scheme heavily depends on the close weather forecasting station. For forecasting horizons more than an hour, this prediction schemes may be also inadequate because weather forecasting errors are accumulated for longer forecasting horizons. Other studies recently used spatiotemporal historical data for solar prediction to overcome these limitations. Without sky imager or satellite images, spatiotemporal-based prediction scheme traces the indirect showing of cloud image using the spatial information; this means that the spatiotemporal historical data inherently have information about cloud cover and cloud movement.

Energy Storage

No matter how the forecasting of loads and generations is accurate, there are inevitable forecasting errors, which may hinder the reliable operation of power system including microgrids. Thus, it is desirable to have energy storage to buffer the mismatch of prediction and realization (Choi and Kim 2016). The definition of energy storage is stated as “commercially available technology that is capable of absorbing energy, storing it for a period of time, and thereafter dispatching

Intelligence and Trading with Energy Storage and Renewable Generation of Microgrids, Fig. 1 Peer-to-peer energy trading of microgrids

the energy” by the California Renewable Energy Sources Act. Furthermore, having energy storage is good for strategic bidding in energy markets thanks to the flexibility of supplying and absorbing energy. Typically, lithium-ion battery is used for energy storage spanning from tens of kWh for electric vehicles/households to MWh for substation level.

Using energy storage, it is beneficial to charge and discharge energy over appropriate time intervals and encourage microgrids to consume stored energy over peak times, or to shift their usage time for matching energy supply through financial incentive programs, e.g., time-of-use, demand response and peak shift.

In utilizing energy storage, one of the essential factors to consider is battery degradation; due to currently high energy storage prices, it is important to extend battery lifetime as much as possible by properly managing its charging and discharging schedule. If energy storage is designed to schedule without considering battery degradation, battery performance deteriorates rapidly in time, and battery cannot be fully exploited economically. Hence, battery degradation characteristics should be jointly considered in the scheduling process. Note that batteries transform chemical energy to electrical energy (and vice versa) by controlling electron flow between positive and negative electrodes, each of which has different chemical potential. Consequently, battery performance highly depends on chemical

substances in addition to temperature, depth of discharge (DoD), charging and discharging rate, and battery type, etc.

Key Applications: Peer-to-Peer Energy Trading

As discussed so far, intelligent microgrids can predict their electric loads and renewable generations and also know how to leverage energy storage. Then, microgrids can participate in energy markets including P2P energy trading. Specifically, it is desirable to develop a market mechanism for distribution network so that microgrids sell energy to other microgrids in the same distribution network, rather than selling to a utility who suggests a cheaper price. Obviously, P2P energy trading is beneficial to both the sellers and the buyers compared to the trading with the utility because it reduces the redundant intermediate process and the associated profit margin of the operator. However, it is not straightforward to agree on the trading price, which should be indifferent to sellers or buyers. Furthermore, P2P energy trading should be better to achieve social welfare, i.e., minimize the total cost of energy generation usage. If so, regulators have no reason not to support P2P energy trading by providing legitimate support to open a new market (Fig. 1).

Designing a P2P energy trading mechanism considering physical constraints, power flows, and social welfare is still a challenging problem, and the question is *who sells how much energy to whom at what price and why?* Specifically, (1) how to determine a systematic bargaining process in terms of the price, which is not biased toward either sellers or buyers, and the quantity, (2) how to realize a P2P energy trading for networked microgrids even if there is no dedicated distribution line between two microgrids, and (3) how to design a market mechanism which minimizes the total cost considering physical network constraints and power flows in the distribution network.

Definitions

Power line communication (PLC) refers to a communication method that reuses existing electrical wiring for data transmission between two communication entities. The technique permits the seamless implementation of a communication system without the need for an additional wiring infrastructure. The broadcast nature of data transmission over power lines creates mutual interference between PLC links that can be mitigated through optimized transmission strategies, such as interference alignment (IA). IA allows interfering users to transmit simultaneously by consolidating the space spanned by the interference at receivers within a small number of signaling dimensions while keeping the desired signals separable from interference so that they can be recovered interference-free.

PLC Medium

Data transmission over power lines is an attractive solution for providing communication services, even in hard-to-reach areas through the reuse of existing power grid infrastructures (Lampe et al. 2016). In an in-home electrical network, for example, one can exploit the phase-neutral (P-N) port to enable PLC as a single-input single-output (SISO) system. Besides, in many countries power line networks deploy multiconductor cables, e.g., an additional earth (E) wire, which creates more feeding and receiving possibilities. Therefore, it is also possible to transmit and receive data over multiple conductors and employ spatial processing via well-established multi-input multi-output (MIMO) technology to enable high-data-rate services (see Fig. 1) (Berger et al. 2014).

While at the surface the power line looks to be well-suited for the data transmission, it is not specifically designed for that purpose and is generally considered as a hostile medium for the data communication. With regard to the signal transmission, the PLC channel exhibits high-frequency selectivity due to frequency-dependent power line characteristics and multiple branches in the power line network. Furthermore, owing to changes in network topology or variation of loads with the mains cycle, the PLC channel may also be time varying. This is complemented by a potentially harsh noise environment, where significant noise originates from loads connected to the power line network (Lampe et al. 2016).

Interference in PLC

A closer look at the signal transmission over power lines would reveal that the data communication is essentially an unintended broadcast transmission, since the communication signals can travel through the electricity grid. The broadcast nature of the PLC channel leads to inter-user interference between the feeding and receiving ports that are in close proximity. Therefore, the system performance (e.g., sum-rate) becomes limited by the underlying mutual interference present in the PLC network. As it is illustrated in Fig. 1, simultaneous

pair-wise data communication (i.e., at the same time-frequency resource) between each feeding and receiving port would resemble data transmission and interference scenario in wireless interference networks (Etkin et al. 2008). Another communication protocol is illustrated in Fig. 2, where each feeding port may have signals intended for each of the receiving ports in the network. This is alike the data communication over the wireless X-network (Cadambe and Jafar 2008a).

Noise in PLC

As mentioned above, noise is considered as a major bottleneck for data communication over power lines. It often possesses a richer structure than the additive white Gaussian noise (AWGN) that is generally assumed in many communication system scenarios. PLC noise may have both stationary and nonstationary components (Cano et al. 2016; Cortés et al. 2010). The stationary component, often referred to as the background noise, typically arises from the various components connected to and/or outside of the power line network that can be time varying as well. The nonstationary noise component, which is impulsive in nature, occurs due to power supplies and switching transients. Besides, practical measurements show that the noise across the multiple receiving ports in MIMO PLC may also be spatially colored (Schwager et al. 2012).

Traditional Approaches to Mitigate Interference

Generally, there are three ways to deal with interference in communications networks. First, if the interference is strong, the interfering signal can be decoded, and hence the desired signal can be separated at the receiving port (Sato 1981). Second, when the interference is weak, the interfering signal can be treated as an additional noise (Annapureddy and Veeravalli 2008). On the other hand, when the strength of the interference is comparable to the desired signal, the conventional wisdom is to avoid interference by orthogonalizing the PLC medium either in time

Interference Alignment for Power Line Communications, Fig. 1

An illustration of a MIMO interference network, where each transmitter (Tx 1 and Tx 2) sends two data streams to its paired receiver (Rx 1 and Rx 2, respectively). Solid and dashed arrows denote desired signal and interference, respectively

Interference Alignment for Power Line Communications, Fig. 2

An illustration of a PLC X-network, where each transmitter (Tx 1 and Tx 2) has data to transmit to each of the two receivers (Rx 1 and Rx 2) in the network. Solid and dashed arrows denote desired signal and interference, respectively

or frequency domain. The use of this technique is found in time- or frequency-division multiple-access-based PLC systems (Brown 1998). Therefore, in a K -user PLC network, each user would only get $\frac{1}{K}$ of the total resources per channel use. In such a network where the transmission from any feeding port interferes reception at all other receiving ports, there will be $K - 1$ interfering signals. In general, K signaling dimensions will be needed to recover the desired signal at each receiving port. This poses the fundamental question – is it possible to do any better, i.e., recover the desired signal within a reduced signaling dimension, and if so, how many signaling dimensions are really needed?

Advanced Solution to Mitigate Interference: Interference Alignment

The above question was solved using the notion of interference alignment (IA), which was introduced as an approach to maximize the interference-free signal space for the desired user (Maddah-Ali et al. 2006, 2008; Cadambe and Jafar 2008b). That is to say, if the interference signals could be consolidated into a reduced signaling dimension so that they do not span the entire signal space at the receiver, while at the same time the desired signal could avoid falling into the interference space, it would be possible to recover the desired signal interference-free. This

Interference Alignment for Power Line Communications, Fig. 3 An illustration of the 3-user IA for a 3-conductor cable MIMO PLC interference network achievable via two spatial signaling dimensions. (Illustration adopted from Jafar 2011, Fig. 3.4.)

is done via the technique of IA. The alignment of the interference can be obtained in time domain (e.g., via symbol extension), in frequency domain (e.g., over multiple subchannels), or in spatial domain (e.g., via MIMO transmission). As it is illustrated in Fig. 3 for a MIMO PLC network with three conductors and thus two spatially multiplexed signals, all three users can communicate simultaneously over the spatial domain via two signaling dimensions. At each receiver, two interfering signals are aligned over a signaling dimension, while the desired signal is received interference-free on the second dimension. The idea is considered to be a breakthrough since now interference networks, e.g., the PLC network, can achieve a much higher rate employing this transmission technique (Jafar 2011).

IA for PLC Networks

While IA has been extensively studied in the context of wireless communications, only recently the researchers have shown the benefits of the IA for PLC systems (Rahman and Lampe 2015, 2017, Submitted). In this regard, relevant algorithms of the IA transmission for different PLC

networks and key performance results are presented below.

IA for MIMO PLC Interference Networks

Following the successful application of iterative IA algorithms, such as the minimum interference leakage (Min-IL) and the maximum signal-to-interference-plus-noise ratio (Max-SINR) algorithms in MIMO wireless communications (Gomadam et al. 2011), they were studied in the context of MIMO PLC networks (Rahman and Lampe 2015). The Min-IL algorithm is designed to iteratively minimize the leakage interference power at each receiver in order to find the optimal IA filters. To this end, the quality of IA performance is measured by the power of the leakage interference at each receiver. One giveaway of the Min-IL algorithm is that it only seeks to achieve perfect IA and makes no attempt in maximizing the desired signal power. The Max-SINR algorithm, on the other hand, chooses the IA filters in a way that maximizes the SINR at the receivers, instead of only minimizing the leakage interference (Gomadam et al. 2011).

In Rahman and Lampe (2015), the Min-IL algorithm has been used to confirm the feasibility of the IA for a MIMO PLC interference network as shown in Fig. 3. To that end, the broadband PLC transmission using the frequency band from 2 to 30 MHz and multicarrier modulation using orthogonal frequency-division multiplexing (OFDM) was considered. In the presence of AWGN, the performance results obtained using the Max-SINR algorithm suggest that the sum-rate gain with IA over orthogonal transmission techniques is around 30% for the considered 3-user 2×2 (3-conductor cable) MIMO PLC network. The research findings also indicate some disparity in comparison to the IA performance in wireless communications owing to shared PLC channels.

The study in Rahman and Lampe (2015) has been extended by considering measured MIMO PLC noise and specifically the impact of the spatial noise correlation on the system performance in Rahman and Lampe (2017, Submitted). Two network configurations, i.e., transmission using the P-E/N-E and the P-N/N-E ports, are

Interference Alignment for Power Line Communications, Fig. 4

Comparison of the sum-rate performances among different IA designs and orthogonal transmission across P-E/N-E ports for a noise dataset collected in Xirivella, Spain. The matched IA design outperforms the mismatched IA design assuming uncorrelated noise, as well as the cases of actually uncorrelated noise and orthogonal transmission

studied. In particular, the study quantified the gains of a matched IA design over that of a mismatched one, where the computation of the IA filters ignores the spatial noise correlation. For a noise dataset from Xirivella, Spain (Schwager et al. 2012), which has an average noise power spectral density of about -74 dBm/Hz, it is found that the average rate gains of the matched over the mismatched IA design are around 30% and 10% across P-E/N-E and P-N/N-E receiving ports with spatial noise correlation coefficients 0.57 and 0.22, respectively (Rahman and Lampe 2017, Submitted). This suggests that the higher the spatial correlation across receiving ports (e.g., across P-E/N-E ports), the larger the rate gains. The study also reveals that the spatial noise correlation actually helps improve the system sum-rate. As shown in Fig. 4, the design considering the spatial noise correlation, i.e., transmission scheme 1, outperforms the mismatched design assuming uncorrelated noise (scheme 2), as well as the cases of actually uncorrelated noise (scheme 3) and orthogonal transmission (scheme 4). The performance benefits hold even when the orthogonal transmission is supplied with 3 times the transmit power, in which case the total transmit power induced into the network is the same as for IA where all three users transmit simultaneously (Rahman and Lampe 2017, Submitted).

IA for SISO PLC X-Networks

Another seemingly feasible idea that was recently attempted to enable IA for the SISO PLC X-network (as shown in Fig. 2) was the technique of blind interference alignment (BIA) (Lampe et al. 2017). The key advantage of a BIA scheme is that it does not require the channel state information be available at the transmitter (Gou et al. 2011; Jafar 2012). However, the BIA scheme requires that the channel seen by each receiving port changes following a specific pattern. The desired patterns of the channel variations over time slots are shown in Fig. 5. It is meant to facilitate the interference cancellation at a given receiving port. One possibility to induce these channel changes is by impedance modulation as suggested in Fig. 5. However, even though the load modulation changes the channel transfer characteristics over time slots, it has been demonstrated based on transmission line modeling of the PLC channel to be ineffective for blind IA (Lampe et al. 2017).

Achievability of the BIA for PLC X-Networks

To control the channel response to a desired receiving port while keeping channel responses to other receiver ports unchanged can be achieved via a concept similar to antenna-staggering in the

Interference Alignment for Power Line Communications, Fig. 5 An illustration of the impedance modulation in order to achieve desired channel patterns over three time slots (Illustration adopted from Jafar 2011, Fig. 4.9), which has been proved to be ineffective for the blind interference alignment in PLC networks

Interference Alignment for Power Line Communications, Fig. 6

An illustration of the transmission scheme for the achievability of blind IA for the PLC X-network using multiple receiving ports

Interference Alignment for Power Line Communications, Fig. 7

A comparison of the multiplexing gains as a function of the transmitter side SNR (on the x-axis) for the proposed BIA and orthogonal transmissions

case of wireless communications. However, this technique requires the use of multiple receiving ports, i.e., a multiconductor structure as in MIMO or SIMO PLC networks. Figure 6 shows such a MIMO PLC X-network with switches at the receiving end to alternate between the receiving ports. The switching between the receiver ports essentially serves the same purpose of antenna switching in wireless communications (Gou et al. 2011). Since switching at a given receiving port has negligible impact on the channel response to the other receiving port due to the attached impedance in parallel as shown in Fig. 6, it can produce the desired channel patterns as illustrated in Fig. 5 for the realization of blind IA. The simulation of the proposed BIA scheme is carried out assuming a distance of 20 m between the nodes. The PLC transmitters and receivers are terminated with load resistances chosen from the

range between 25 and 100 Ω . Each transmitter sends a single data stream intended for each of the receivers in the network. Both the transmitters are provided with the same power and AWGN is assumed. For the evaluation of performance, the multiplexing gain is calculated via computing the slope of total sum-rates as a function of the transmitter side signal-to-noise ratio (SNR). The results in Fig. 7 suggest that a multiplexing gain of 4/3 can be achieved with BIA, which exceeds the multiplexing gain for an orthogonal transmission. The maximum multiplexing gain that is achievable for the considered PLC X-network configuration in Fig. 6 is 4/3 (Gou et al. 2011). This confirms the effectiveness of the BIA with the proposed multiconductor transmission scheme.

Conclusions

While IA has been widely studied in wireless communications, only recently this technique has been investigated in the context of PLC. This chapter presents a synopsis on the IA techniques for PLC networks. To this end, IA techniques are discussed and relevant results are summarized. While IA is shown to improve the sum-rate performance, the seemingly simple realization of blind IA using the impedance modulation is not effective for PLC X-networks. However, a transmission technique similar to antenna-staggering in wireless communications via the use of multiple receiving ports is able to achieve the maximum multiplexing gain for blind IA over this network.

Cooperative transmitter-side interference management

Definitions

Interference alignment (IA) is a baseband signal processing technique at multiple cooperative transmitters to achieve the directional alignment of interfering signals and preserve the resolvability of desired signals at each receiver.

Historical Background

Interference alignment (IA) is a recent advance in interference management. It offers a new direction to manage the mutual interference in cooperative wireless networks. IA is a transmitter-side signal processing technique. It refers to the construction of baseband signals at multiple cooperative transmitters so that the radio signals are aligned to the same direction at their unintended receivers while remaining resolvable at their intended receivers. Despite similar ideas having been around for many years, the concept of IA was coined by Cadambe and Jafar in a seminar paper

Cadambe and Jafar (2008) in 2008, which showed that by using IA, the K -user interference channel can achieve $K/2$ degrees of freedom (DoFs) regardless of the number of users in the channel. This result is significant as it shows that the DoFs (first-order approximation of capacity) of a wireless interference network can increase linearly with the number of users in the network. This scaling-law result challenged the conventional understanding of “wireless networks are interference limited” and thus attracted a large amount of research attention in wireless communication community. Since then, the concept of IA has been applied to a variety of wireless networks in increasingly sophisticated forms, such as the K -user MIMO interference channel (Bresler et al. 2014), the cellular network (Suh et al. 2011), the MIMO Y channel (Lee et al. 2010), the X network with arbitrary number of users, and the complex interference channel. An information theoretic tutorial of IA in different wireless networks is presented in Jafar (2011). In addition to advances in theory, IA has been studied on wireless testbeds to explore its practicality and performance in real-world wireless systems. This research line has also produced many exciting results on IA (see, e.g., El Ayach et al. 2010 and Gollakota et al. 2009).

Foundations

In wireless networks, based on the domain in which the signals are manipulated at the cooperative transmitters, the results of IA can be divided into different categories: space-domain IA (SD-IA), frequency-domain IA (FD-IA), and time-domain IA (TD-IA).

Space-Domain IA SD-IA refers to a joint construction of baseband signals at the transmitters by precoding their outgoing data streams onto their multiple antennas so that at each receiver, the interfering streams are overlapped in the space domain, while the desired data streams remain resolvable. Since the interfering streams are overlapped at a receiver, the dimension of

the interference subspace is reduced, making it possible to receive more concurrent data streams free of interference at this receiver. Therefore, to achieve SD-IA in a network, each node must have multiple antennas.

Figure 1 shows an example of SD-IA in a three-link network, where each node has two antennas. Without using SD-IA, this network can transport two data streams from its transmitters to its receivers. In contrast, by using SD-IA, this network can transport three data streams from its transmitters to its receivers. The SD-IA scheme for this network is illustrated in Fig. 1. At transmitter T_i , denote $\mathbf{u}_i^k$ as the precoding vector for the k th stream. Denote $\mathbf{H}_{ji}$ as the channel matrix between receiver R_j and transmitter T_i . Then, SD-IA can be achieved at the receivers through jointly constructing the precoding vectors as follows: $\mathbf{u}_1^1 = \text{eigvec}(\mathbf{H}_{21}^{-1}\mathbf{H}_{23}\mathbf{H}_{13}^{-1}\mathbf{H}_{12}\mathbf{H}_{32}^{-1}\mathbf{H}_{31})$, $\mathbf{u}_2^1 = \mathbf{H}_{32}^{-1}\mathbf{H}_{31}\mathbf{u}_1^1$, $\mathbf{u}_3^1 = \mathbf{H}_{23}^{-1}\mathbf{H}_{21}\mathbf{u}_1^1$, where $\text{eigvec}(\cdot)$ is an eigenvector of a square matrix. It can be verified that by using the above precoding vectors, the interfering streams will be aligned in the same direction at each receiver; and the desired data stream will lie in an independent direction (free of interference) at each receiver, as shown in the figure. Therefore, one data stream can be transported on each link, and a total of three data streams can be transported in this network.

Frequency-Domain IA FD-IA refers to a joint construction of baseband signals at the transmitters by precoding their outgoing data streams onto a set of frequency subcarriers so that at each receiver, its interfering streams are overlapped in the frequency domain, while its desired data streams remain distinguishable. Different from SD-IA, FD-IA does not require the network to have multiple antennas at each node. Instead, it requires the network to have multiple orthogonal frequency channels. As such, FD-IA is particularly suited for OFDM-modulated wireless systems. FD-IA was first studied for cellular networks by Suh and Tse in (2008), in which they proved that a FD-IA scheme could achieve $K/(G\sqrt{K} + 1)^{G-1}$ DoFs for each cell, where G is the number of cells and K is the number of users in a cell. As the number of users in a cell becomes large ($K \rightarrow +\infty$), each cell can achieve one DoF. This means that each cell (base station) can serve its users as if there were no inter-cell interference. In Suh et al. (2011), Suh et al. extended their FD-IA scheme to the downlink of a cellular network and showed that their FD-IA scheme works for the network where feedback information is limited in a cell. In Zeng et al. (2017b), Zeng et al. developed a FD-IA model for a heterogeneous cellular network and proved the feasibility of the FD-IA model.

Figure 2 shows an example of FD-IA in a single-antenna wireless network, which has three orthogonal frequency subcarriers for data trans-

Interference Alignment in Wireless Networks,

Interference Alignment in Wireless Networks,

Fig. 2 An example of FD-IA. A solid arrow line represents data transmission, and a dashed arrow line represents interference

mission. Without FD-IA, this network can transport three data streams from the transmitters to the receivers (one on each subcarrier). By using FD-IA, this network can transport four data streams from the transmitters to the receivers (one on each link). The FD-IA scheme for this network is illustrated in Fig. 2. Denote $\mathbf{H}_{ji}$ as the frequency-domain channel matrix between receiver R_j and transmitter T_i . Due to the orthogonality of the frequency subcarriers, $\mathbf{H}_{ji}$ is a full-rank diagonal matrix, and its k th diagonal entry is channel coefficient of the k th subcarrier. Denote $\mathbf{u}_i^k$ as the precoding vector for the k th outgoing stream at transmitter T_i . For each receiver, it has two desired data streams and two interfering streams. Since the receiver has only three frequency subcarriers, it can decode both its desired data streams free of interference only if its two interfering streams are aligned in the same direction. One precoding scheme that can achieve the desired alignment at both receivers is as follows: $\mathbf{u}_1^1 = \mathbf{u}_{\text{ref}}$, $\mathbf{u}_2^1 = \mathbf{H}_{22}^{-1}\mathbf{H}_{21}\mathbf{u}_1$, $\mathbf{u}_3^1 = \mathbf{u}_{\text{ref}}$, $\mathbf{u}_4^1 = \mathbf{H}_{24}^{-1}\mathbf{H}_{23}\mathbf{u}_3$, where $\mathbf{u}_{\text{ref}}$ is a 3×1 reference vector with nonzero entries. By using the above precoding vectors, it can be verified that at each receiver, the two interfering streams will be aligned in the same direction, and the two desired data streams will lie in two independent directions, as shown in the figure. Therefore, four data streams can be transported over three frequency subcarriers in this network.

FD-IA in the above example appears similar to SD-IA in Fig. 1. But there is a fundamental difference between them. The design of FD-IA

relies on the characteristics of frequency-domain channels, which are diagonal matrices with each diagonal entry being the channel coefficient of a frequency subcarrier. In contrast, the design of SD-IA relies on the characteristics of space-domain channels, which are full (rather than diagonal) matrices with each entry being the channel coefficient from a transmit antenna to a receive antenna. Due to this fundamental difference, a direct extension of an IA scheme from the space domain to the frequency domain by simply treating an antenna element as a frequency subcarrier is not plausible and may result in an infeasible solution.

Time-Domain IA TD-IA refers to a joint construction of the signals at the transmitters in the time domain so that at each receiver, the interfering signals are aligned to the same direction, while the desired signals are free of interference. TD-IA can be achieved in different ways. For example, it can be achieved as the FD-IA scheme in Fig. 2 by simply treating each subcarrier as a time slot; it can also be achieved by leveraging the large propagation delays of signal travel (e.g., in underwater acoustic networks). In Grokop et al. (2011), Grokop et al. proposed a TD-IA scheme by exploiting the propagation delays between transmitters and receivers. They showed that by using TD-IA, the spectral efficiency of the K -user interference channel can grow linearly with K if the channel bandwidth is sufficiently large. In Chitre et al. (2012), Chitre et al. developed scheduling algorithms to exploit the benefits of

Interference Alignment in Wireless Networks, Table 1 A summary of SD-IA, FD-IA, and TD-IA

	Application scenarios	CSI at TX	Coordination among TX	SNR requirement at RX	Channel rank requirement
SD-IA	Multi-antenna networks	Required	Required	High SNR regime	Full-rank and independent channels
TD-IA	Networks with large propagation delays	Required	Required	All SNR regime	No requirement
FD-IA	OFDM networks	Required	Required	High SNR regime	Full-rank and frequency-selective channels

TD-IA for throughput improvement in a multiuser network with large propagation delays. In Zeng et al. (2017a), Zeng et al. showed that propagation-delay-based TD-IA can be achieved in a distributed fashion to improve the multi-hop network throughput.

Summary Table 1 summarizes the properties and requirements of these three IA schemes, including their application scenarios, channel state information (CSI) requirement, coordination requirement, signal-to-noise ratio (SNR) requirement, and channel rank requirement.

Key Applications

IA can be used to manage interference for wireless networks that have coordination among their transmitters. An application scenario of IA is enterprise Wi-Fi networks, where the access points (APs) have multiple antennas and are connected via high-speed cables. Another application scenario of IA is cellular wireless networks, where the base stations can cooperate with each other for interference management. In such networks, IA can be used to manage the co-channel (inter-cell) interference so as to improve the network throughput.

Synonyms

Interference correlation; Joint Laplace transform of co-channel interference; Poisson point process

Definitions

Interference characterization refers to mathematically characterizing the co-channel interference generated by concurrent transmissions, in terms of its probability density function, Laplace transform, or expectation, via modeling the influential sources of randomness, including the spatial locations of the interferers, the traffic pattern, the medium access scheme, and the propagation channel.

Background

Due to the scarcity of the radio spectrum, resource (e.g., time, frequency, and code) sharing among multiple wireless transceivers is necessary to enhance the radio spectral efficiency

of wireless ad hoc networks. Because of the broadcast nature of wireless medium, spatially separated concurrent transmissions in the same radio channel inevitably lead to co-channel interference, which is the main performance-limiting factor. As a result, the fundamental step toward analyzing the network-wide performance is the accurate characterization of co-channel interference due to concurrent transmissions.

Two widely used interference models are the protocol interference model and physical interference model (Cardieri 2010). Under the protocol interference model, the impact of co-channel interference on the packet reception is binary (Zhou and Zhuang 2013). In particular, the interference from an unintended transmitter located outside the interference range of a receiver has negligible impact on the packet reception. The interference from an unintended transmitter located within the interference range of a receiver always interrupts the packet reception. The interference range is set based on the signal-to-noise ratio (SNR) threshold required for successful packet reception. On the other hand, under the physical interference model, the power levels of the signals from all unintended transmitters are added, and the sum is considered as interference power at a receiver. A packet is successfully decoded if the signal-to-interference-plus-noise ratio (SINR) observed at the receiver is not smaller than the required reception threshold.

Interference characterization has been attracting more and more attention in recent years. In Gilhousen et al. (1991), the co-channel interference was approximated by a Gaussian random variable, where the mean and variance of co-channel interference are set by using an empirical fitting method. The Gaussian approximation enables tractable performance analysis for fixed topology networks. The Wyner model (Wyner 1994) is another simplified model proposed for interference characterization, which only takes into account the nearest neighboring interferers. Both the Gaussian approximation and the Wyner model cannot accurately characterize the co-channel interference in wireless ad hoc networks, as the co-channel interference depends

on multiple sources of randomness, including the interferers' spatial distribution, the traffic pattern, the medium access scheme, and the propagation channel. Besides, conducting exhaustive simulations can overcome the shortcomings of the Gaussian approximation and the Wyner model by averaging out all the randomness. However, the simulation-based method is always time-consuming and error-prone.

In order to incorporate the randomness of the interferers' spatial locations into interference characterization, a more advanced model based on the point process theory was proposed in Baccelli and Błaszczyszyn (2010). In particular, the spatial locations of concurrent transmitters are modeled as a homogeneous Poisson point process (PPP). By using tools from stochastic geometry, the co-channel interference at any time instant can be characterized in terms of its Laplace transform. Such a model enables accurate performance evaluation for both wireless ad hoc networks (Baccelli et al. 2009) and cellular networks (ElSawy et al. 2017). Based on the Poisson shot noise field theory, the authors in Baccelli et al. (2009) analyzed the outage probability of an opportunistic ALOHA scheme in a mobile ad hoc network (MANET), where the randomness of both the medium access and the spatial locations of the interferers is considered. Moreover, the accuracy of the PPP modeling for the spatial locations of the base stations in large-scale cellular networks was demonstrated in ElSawy et al. (2017).

Cooperative communication is an effective technique, which has the potential to mitigate the detrimental effect of wireless channel impairments by achieving a spatial diversity gain (Sendonaris et al. 2003; Zhuang and Zhou 2013). The process of cooperative communication is generally composed of two phases, namely, information sharing and cooperative transmission phases. In the information sharing phase, the transmitter broadcasts a packet to the potential relays and the intended receiver. In the cooperative transmission phase, the potential relays that overheard the packet act as relays and help forward the packet to the intended receiver. By combining two or more copies of the same

packet transmitted through independent links, a spatial diversity gain is achieved at the receiver. The advantages of cooperative communication in the physical layer have been demonstrated by analyzing different relaying strategies from the information theory point of view. For different application scenarios, the cooperative advantages at the physical layer can be transformed into specific advantages at the link layer, such as enhancing transmission reliability, reducing transmission power, increasing transmission rate, and enlarging network coverage (Shan et al. 2009; Zhuang and Ismail 2012).

Interference Characterization for Cooperative Communication

Different from a direct link, a cooperative link is characterized by the extra relay(s) and two-phase transmission. As a result, the co-channel interference generated by a cooperative link is different from the co-channel interference generated by a direct link, as an additional relay or relays participate in the transmission of one packet. In other words, the cooperative links redistribute the interference over a large-scale wireless network due to relay transmissions (Zhou and Zhuang 2015, 2016). In order to accurately characterize the network-wide performance of cooperative communication, the interference redistribution due to concurrent cooperative transmissions should be taken into account. Thereby, an interference characterization framework for cooperative communication under the physical interference model is presented as follows.

Consider a two-dimensional network coverage area with spatially random transmitters, relays, and receivers. The spatial locations of the transmitters are assumed to follow a homogeneous PPP, denoted as $\Phi_S = \{s_1, s_2, \dots\}$, with density λ_S , which represents the average number of transmitters per unit area. Each transmitter (e.g., S_i) is associated with a receiver (e.g., D_i), which is located at L meters away with a random direction. The relays (e.g., R_i) do not have their own packets to transmit and receive, and they are always willing to help forward packets for

the transmitters. The spatial locations of the relays also form a homogeneous PPP, denoted as $\Phi_R = \{r_1, r_2, \dots\}$, with density λ_R . Due to the stationary property of the homogeneous PPP, the co-channel interference observed at the typical transmitter-receiver pair, indexed as $i = 0$, follows the same distribution with that at any transmitter-receiver pair in the network. Without loss of generality, the typical transmitter and receiver are located at $(L, 0)$ and $(0, 0)$, respectively. The channel between any two transceivers suffers from Rayleigh fading and path loss. All channel fading coefficients are assumed to be independent and identically distributed (i.i.d.) random variables with unit mean. The path loss between transmitter S_i and receiver D_j is denoted as $g(s_i - d_j)$.

All transmitters and relays transmit with the same power, which is normalized to one. Each transmitter always has a packet for transmission and makes an independent decision on the transmission mode (i.e., direct transmission or cooperative transmission). Different criteria (e.g., the number of relays available) can be applied to enable opportunistic cooperation. This entry considers a general case and denotes the probability that each transmitter-receiver pair enables cooperative transmission as p . Hence, by applying the independent thinning property of the PPP, the

final cooperative transmission set (consisting of the spatial locations of transmitters of cooperative links) and direct transmission set are independent and denoted as Φ_C and Φ_D with densities $\lambda_C = p\lambda_S$ and $\lambda_D = (1 - p)\lambda_S$, respectively.

Relay selection plays a pivotal role in determining the performance of a cooperative transmission scheme. An efficient relay selection scheme should select the best relay among randomly positioned relays while taking into account the spatial frequency reuse. Various relay selection schemes (e.g., Zhou and Zhuang 2017) can be applied. This entry does not specify the relay selection scheme, and the interference characterization method presented here can be modified to fit specific relay selection schemes.

For both direct and cooperative transmission, each packet is transmitted in one time slot. For cooperative transmission, each time slot is divided equally into two sub-time slots. In the first sub-time slot, each transmitter transmits a packet to its intended receiver. As shown in Fig. 1a, the aggregate interference power observed at the relay (e.g., R_k) of the typical transmitter-receiver pair in the first sub-time slot can be expressed as

$$I_{R_k:1}(\Phi_D, \Phi_C) = I_{DR_k:1}(\Phi_D) + I_{CR_k:1}(\Phi_C), \quad (1)$$

Interference Characterization for Cooperative Communications in Mobile Ad Hoc Networks, Fig. 1 An illustration of the interference power, originating from both the direct and cooperative links over the network, observed by relay R_k and destination D_0 in the first and second sub-time slots. Each circle, triangle, and square

represent a source, selected relay, and destination, respectively. The solid and dashed lines represent the transmitted signal and interference, respectively. (Reproduced with permission from Springer.) (a) Transmission in the first sub-time-slot. (b) Transmission in the second sub-time-slot

where $I_{DR_k:1}(\Phi_D) = \sum_{s_i \in \Phi_D} H_{S_i R_k:1} g(s_i - r_k)$ is the interference power at relay R_k from the transmitters of direct links, $I_{CR_k:1}(\Phi_C) = \sum_{s_j \in \Phi_C} H_{S_j R_k:1} g(s_j - r_k)$ denotes the interference power at relay R_k from the transmitters of cooperative links, and $H_{S_i R_k:1}$ denotes the fading coefficient between transmitter S_i and relay R_i in the first sub-time slot.

Taking into account the interference redistribution incurred by cooperative transmission, as shown in Fig. 1b, the aggregate interference power observed at receiver D_0 in the first and second sub-time slots can be expressed respectively as

$$\begin{aligned} I_{D_0:1}(\Phi_D, \Phi_C) &= I_{DD_0:1}(\Phi_D) + I_{CD_0:1}(\Phi_C), \\ I_{D_0:2}(\Phi_D, \Phi_F) &= I_{DD_0:2}(\Phi_D) + I_{FD_0:2}(\Phi_F), \end{aligned} \quad (2)$$

where $I_{DD_0:1}(\Phi_D) = \sum_{s_i \in \Phi_D} H_{S_i D_0:1} g(s_i)$ and $I_{DD_0:2}(\Phi_D) = \sum_{s_i \in \Phi_D} H_{S_i D_0:2} g(s_i)$ denote the aggregate interference powers from the transmitters of direct links in the first and second sub-time-slots, respectively, and $I_{CD_0:1}(\Phi_C) = \sum_{s_j \in \Phi_C} H_{S_j D_0:1} g(s_j)$ and $I_{FD_0:2}(\Phi_F) = \sum_{r_m \in \Phi_F} H_{R_m D_0:2} g(r_m)$ denote the aggregate interference powers from the

transmitters and selected relays of cooperative links in the first and second sub-time slots, respectively. Here, Φ_F denotes the PPP formed by the spatial locations of the selected relays that forward the packets in the second sub-time slot.

As the spatial locations of the transmitters of direct links in both sub-time slots are the same, interference powers $I_{DD_0:1}(\Phi_D)$ and $I_{DD_0:2}(\Phi_D)$ are temporally correlated. Because the transmitter (e.g., S_j) is always located adjacent to its selected relay (e.g., R_m) for each cooperative link, interference powers $I_{CD_0:1}(\Phi_C)$ and $I_{FD_0:2}(\Phi_F)$ are also temporally correlated. In summary, the interference powers observed at receiver D_0 in two sub-time slots, i.e., $I_{D_0:1}(\Phi_D, \Phi_C)$ and $I_{D_0:2}(\Phi_D, \Phi_F)$, are temporally correlated. On the other hand, the relay of the typical transmitter-receiver pair and the typical receiver are geographically close, and they suffer from the interference generated by the same or adjacent interferers. Hence, the interference powers $I_{R_k:1}(\Phi_D, \Phi_C)$ and $I_{D_0:1}(\Phi_D, \Phi_C)$ or $I_{D_0:2}(\Phi_D, \Phi_F)$ are spatially correlated.

Based on the above discussions, the joint Laplace transform of interference powers $I_{D_0:1}(\Phi_D, \Phi_C)$ and $I_{D_0:2}(\Phi_D, \Phi_F)$ is given by

$$\begin{aligned} \mathcal{L}(\zeta_1, \zeta_2) &= \mathbb{E} \left[\exp(-\zeta_1 I_{D_0:1}(\Phi_D, \Phi_C) - \zeta_2 I_{D_0:2}(\Phi_D, \Phi_F)) \right] \\ &\stackrel{(a)}{=} \mathbb{E} \left[\exp(-\zeta_1 I_{DD_0:1}(\Phi_D) - \zeta_2 I_{DD_0:2}(\Phi_D)) \right] \\ &\quad \times \mathbb{E} \left[\exp(-\zeta_1 I_{CD_0:1}(\Phi_C) - \zeta_2 I_{FD_0:2}(\Phi_F)) \right], \end{aligned} \quad (3)$$

where (a) follows by substituting (2) and from the independence between PPP Φ_D and PPP Φ_C or PPP Φ_F .

By taking the Laplace transform of the fading coefficients between the interferers and the typical receiver, $\mathcal{A}_1 = \mathbb{E} \left[\exp(-\zeta_1 I_{DD_0:1}(\Phi_D) - \zeta_2 I_{DD_0:2}(\Phi_D)) \right]$ can be computed by

$$\begin{aligned} \mathcal{A}_1 &= \mathbb{E} \left[\prod_{s_i \in \Phi_D} \frac{1}{(1 + \zeta_1 g(s_i)) (1 + \zeta_2 g(s_i))} \right] \\ &\stackrel{(a)}{=} \exp \left(-\lambda_D \int_{\mathbb{R}^2} \left(1 - \frac{1}{(1 + \zeta_1 g(s)) (1 + \zeta_2 g(s))} \right) ds \right), \end{aligned} \quad (4)$$

where (a) follows from the probability generating functional (PGFL) of the PPP.

Similarly, $\mathcal{A}_2 = \mathbb{E}[\exp(-\zeta_1 I_{CD_0:1}(\Phi_C) - \zeta_2 I_{FD_0:2}(\Phi_F))]$ is given by

$$\begin{aligned} \mathcal{A}_2 &= \mathbb{E} \left[\left(\prod_{s_i \in \Phi_C} \frac{1}{1 + \zeta_1 g(s_i)} \right) \left(\prod_{r_m \in \Phi_F} \frac{1}{1 + \zeta_2 g(r_m)} \right) \right] \\ &\stackrel{(a)}{=} \mathbb{E} \left[\left(\prod_{s_i \in \Phi_C} \frac{1}{1 + \zeta_1 g(s_i)} \right) \left(\prod_{s_i \in \Phi_C} \left(\frac{1 - q_e}{1 + \zeta_2 g(s_i + \tau)} + q_e \right) \right) \right] \\ &\stackrel{(b)}{=} \exp \left(-\lambda_C \int_{\mathbb{R}^2} \left(1 - \frac{1}{1 + \zeta_1 g(s)} \left(\frac{1 - q_e}{1 + \zeta_2 g(s + \mathbb{E}_\tau[\tau])} + q_e \right) \right) ds \right), \end{aligned} \quad (5)$$

where q_e is probability that no relays are available, τ denotes the coordinate difference between the transmitter and the selected relay, (a) follows from the transformation between PPP Φ_C and PPP Φ_F , and (b) follows from the PGFL of the PPP. Note that both q_e and τ depend on the adopted relay selection scheme.

By substituting (4) and (5) into (3), the joint Laplace transform of interference powers

$I_{D_0:1}(\Phi_D, \Phi_C)$ and $I_{D_0:2}(\Phi_D, \Phi_F)$ can be obtained. Following the similar steps, the Laplace transform of each interference power (e.g., $I_{D_0:1}(\Phi_D, \Phi_C)$ or $I_{D_0:2}(\Phi_D, \Phi_F)$) can also be derived.

On the other hand, the joint expectation of interference powers $I_{D_0:1}(\Phi_D, \Phi_C)$ and $I_{D_0:2}(\Phi_D, \Phi_F)$ is another important metric, which is given by

$$\begin{aligned} \mathcal{E} &= \mathbb{E} [I_{D_0:1}(\Phi_D, \Phi_C) I_{D_0:2}(\Phi_D, \Phi_F)] \\ &= \mathbb{E} [I_{DD_0:1}(\Phi_D) I_{DD_0:2}(\Phi_D)] + \mathbb{E} [I_{DD_0:1}(\Phi_D) I_{FD_0:2}(\Phi_F)] \\ &\quad + \mathbb{E} [I_{CD_0:1}(\Phi_C) I_{DD_0:2}(\Phi_D)] + \mathbb{E} [I_{CD_0:1}(\Phi_C) I_{FD_0:2}(\Phi_F)]. \end{aligned} \quad (6)$$

As PPP Φ_D is independent of PPP Φ_C and PPP Φ_F , the following equations hold

$$\mathbb{E} [I_{CD_0:1}(\Phi_C) I_{DD_0:2}(\Phi_D)] = \lambda_C \lambda_D \left(\int_{\mathbb{R}^2} g(s) ds \right)^2. \quad (7)$$

$$\mathbb{E} [I_{DD_0:1}(\Phi_D) I_{FD_0:2}(\Phi_F)] = \lambda_D \lambda_F \left(\int_{\mathbb{R}^2} g(s) ds \right)^2,$$

As PPP Φ_C and PPP Φ_F are not independent of each other, the mean product of interference powers $I_{CD_0:1}(\Phi_C)$ and $I_{FD_0:2}(\Phi_F)$ is given by

$$\begin{aligned} \mathbb{E} [I_{CD_0:1}(\Phi_C) I_{FD_0:2}(\Phi_F)] &\stackrel{(a)}{=} \mathbb{E} \left[\left(\sum_{s_j \in \Phi_C} g(s_j) \right) \left(\sum_{r_m \in \Phi_F} g(r_m) \right) \right] \\ &\stackrel{(b)}{=} \mathbb{E} \left[\left(\sum_{s_j \in \Phi_C} g(s_j) \right) \left(\sum_{s_j \in \Phi_C} (1 - q_e) g(s_j + \tau) \right) \right] \end{aligned}$$

$$\begin{aligned}
&= \mathbb{E} \left[\sum_{s_j \in \Phi_C} (1 - q_e) g(s_j) g(s_j + \tau) \right] \\
&\quad + \mathbb{E} \left[\sum_{s_i, s_j \in \Phi_C, s_i \neq s_j} (1 - q_e) g(s_j) g(s_j + \tau) \right] \\
&\stackrel{(c)}{=} \lambda_F \int_{\mathbb{R}^2} g(s) \mathbb{E}_\tau [g(s + \tau)] ds + \lambda_C \lambda_F \left(\int_{\mathbb{R}^2} g(s) ds \right)^2, \tag{8}
\end{aligned}$$

where $\lambda_F = \lambda_C(1 - q_e)$ denotes the spatial density of PPP Φ_F , (a) follows as the channel fading coefficients are independent random variables with unit mean, (b) follows from the transformation between PPP Φ_C and PPP Φ_F , and (c) follows from Campbell's theorem and second-order product density formula of the PPP.

Similarly, by setting $\tau = (0, 0)$, the following equation holds

$$\begin{aligned}
&\mathbb{E} [I_{D_{0:1}}(\Phi_D) I_{D_{0:2}}(\Phi_D)] \\
&= \lambda_D \int_{\mathbb{R}^2} (g(s))^2 ds + \lambda_D^2 \left(\int_{\mathbb{R}^2} g(s) ds \right)^2. \tag{9}
\end{aligned}$$

By substituting (7), (8), and (9) into (6), the joint expectation of interference powers $I_{D_{0:1}}(\Phi_D, \Phi_C)$ and $I_{D_{0:2}}(\Phi_D, \Phi_F)$ can be obtained. Following the similar steps, the expectation of each interference power (e.g., $I_{D_{0:1}}(\Phi_D, \Phi_C)$ or $I_{D_{0:2}}(\Phi_D, \Phi_F)$) can also be obtained.

The joint Laplace transform and joint expectation of co-channel interference due to concurrent cooperative transmissions are useful for performance analysis in various large-scale networks. For example, they can be used to evaluate the spatial and temporal correlation levels of co-channel interference, to derive the network-wide performance (e.g., outage probability, achievable ergodic rate, and transmission capacity), and to estimate the average energy that can be harvested by exploiting co-channel interference.

Conclusions

In this entry, the backgrounds of the interference model, the interference characterization, and the cooperative communication are reviewed. Then, an interference characterization framework for cooperative communication is presented, where the co-channel interference is characterized in terms of the joint Laplace transform and the joint expectation. Finally, the applications of interference characterization are discussed.

Definitions

As a key component of urban rail transit systems, *communications-based train control* (CBTC) is an automated train control system using train-ground communications to ensure efficient operation of rail vehicles. In addition to CBTC systems, passenger information systems (PISs) are adopted in urban rail transit systems to improve quality of service (QoS) offered to customers. The interference between CBTC systems and PISs is an important factor impacting QoS of both CBTC systems and PISs. With recent advances in cognitive dynamic systems, a cognitive control approach is proposed to interference mitigation considering the co-existence of CBTC systems and PISs, where the notion of information gap is adopted to quantitatively describe effects of interference on CBTC and the wireless channel is modeled as a finite-state Markov chain with multiple state transition probability matrices derived from real-field measurements.

Background

Urban rail transit systems are developing rapidly around the world. Due to the huge urban traffic pressure, improving efficiency of urban rail transit systems is in high demand. *Communications-based train control* (CBTC) is adopted to improve utilization of railway network infrastructure and enhance the level of service offered to customers (Zhu et al. 2012). In addition to CBTC systems, *passenger information systems* (PISs) are adopted in urban rail transit systems to improve the quality of service (QoS) offered to customers (Zhu et al. 2011). PISs can provide real-time services (e.g., video) information to passengers at the station or onboard, including arriving and departure time, news, sport games, and advertisements. When emergencies (e.g., fire and terrorist attacks) happen, PISs can supply signs of emergency evacuation. Both CBTC systems and PISs use wireless local area networks (WLANs) as the main method for train-ground communications due to available commercial off-the-shelf (COTS) WLAN equipment with low costs. As a result, *interference* between CBTC systems and PISs is an important factor impacting QoS of both CBTC systems and PISs.

Real-field measurements on coexisting CBTC systems and PISs at Beijing Subway Line 1 show that percentage of packet losses is increased with interference from the PIS even if the associated AP does not change, besides those caused by handoffs (Wang et al. 2015), where CBTC APs working at channel 1 and PIS APs working at channel 6 and there is no overlapping frequency band.

Based on 802.11 protocols, a WLAN station applies the Clear Channel Assessment (CCA) mechanism to detect the channel state (busy or idle). According to measurement results, it is possible that the power of the PIS wireless link “leaks” into the adjacent channel (i.e., channel 1), which can cause the CBTC WLAN equipment to misjudge the channel state. Therefore, the interfered equipment could perform unnecessary backoff procedures or suffered from collisions,

which can lead to packet losses. As a result, cognitive control could be used to mitigate the inference issues (Wang et al. 2017).

A Cognitive Control Approach to Mitigate Impacts of Interference from the PIS

Continuous bidirectional wireless communications between the mobile station (MS) and access points (APs) are adopted in modern CBTC systems to guarantee high efficiency and reliability of train operation, which can connect wayside equipment and onboard equipment. Similarly to CBTC systems, a PIS consists of onboard devices, ground equipment, and a network. Onboard devices include cameras, screens, and PIS MSs, while ground equipment includes a video server, a monitor center, and PIS APs. PIS train-ground communications ensure passengers onboard can get real-time information from the video server and the monitor center can real-time receive monitoring pictures of the train interior and the station, as shown in Fig. 1.

The proposed cognitive control approach dynamically makes decisions, such as the packet size, the transmission interval, handoff decisions, and physical layer parameters, in order to guarantee the data transmission between the train and the control center in CBTC systems. Adding a new term about information gap compared with traditional cost function of a quadratic optimal controller, the resulting cost function can be formulated as follows (Haykin et al. 2012).

$$J = (s - \tilde{s})^T W (s - \tilde{s}) + u^T R u + \beta G \quad (1)$$

where G is the information gap and β is a scalar, $\tilde{s}$ is the desired state of the system, s is the actual state of the system, u is the physical control vector, and matrices W and R are applied as desired weights for systems's state and control.

As a result, a cognitive controller on the train should help the CBTC MS to make some decisions through reinforcement learning

Interference Mitigation in Wireless Communications-Based Train Control (CBTC), Cognitive Control Approach, Fig. 1 Coexistence of a CBTC system and a PIS

(RL) (Yu et al. 2006) in order to improve communication performance, which could be implemented at the application layer, the MAC layer, and the physical layer. The action determined at each communication cycle at the k th communication cycle could be denoted as $a_k = \{a_k^s, a_k^i, a_k^h, a_k^m\}$, where a_k^s is the packet size action, a_k^i is the packet interval action, a_k^h is the handoff action, and a_k^m is the multiplexing gain action. The state s_k is denoted as $s_k = \{\gamma_{1k}^l, \gamma_{2k}^l, ID, PLR, PI, PS\}$, where ID is the identification number of the current associated AP, PLR is the packet loss rate, PI is the packet interval, and PS is the packet size. When ID changes, the handoff procedure happens.

According to Eq. (1), the information gap can be defined based on the QoS. QoS indexes could be given as D_k, L_k , where D_k and L_k are the time delay and the number of packet loss at the k th communication cycle and $G_k = \{D_k, L_k\}$. Therefore, the cost function of cognitive control in the paper is shown as follows:

$$J = (s_k - \hat{s}_k) Q (s_k - \hat{s}_k)^T + a_k R a_k^T + \beta G_k G_k^T \quad (2)$$

where $\hat{s}_k$ is the desirable state of the system.

Formulation of the Cognitive Control Approach

The MAC layer model and the physical layer model are needed to formulate the cognitive control approach to mitigate impacts of interference from the PIS. According to the structure of the cognitive control system, the CBTC MS is considered as the perceptual part that can calculate the information gap according to QoS indexes. Based on the information gap, the cognitive controller can make decisions that should be performed on the CBTC MS.

According to the random access scheme of CSMA/CA protocols, a random packet is transmitted after the DIFS time and the backoff time, which is uniformly distributed in the range $[0, CW - 1]$. As a result, $BackoffTime_\alpha = Random([0, CW_\alpha - 1]) \times aSlotTime$, where $aSlotTime$ is a constant time corresponding to IEEE 802.11g standards. CW is the value of contention window which has lower and upper bounds denoted as CW_{min} and CW_{max} . For the first backoff, CW is initialized as CW_{min} . Then, each backoff will double CW until it reaches CW_{max} . The contention window

is kept as $CW_{\max}$ when times of backoff are no less than m . As a result, the probability

$BackoffTime = i$ could be obtained as follows.

$$P(BackoffTime = i) = \begin{cases} \sum_{\alpha=0}^{m-1} \frac{p^\alpha(1-p)}{2^\alpha CW_{\min}} + \frac{p^m}{CW_{\max}} & 1 \leq i \leq CW_{\min} \\ \sum_{\alpha=\lfloor \log_2 i \rfloor}^{m-1} \frac{p^\alpha(1-p)}{2^\alpha CW_{\min}} + \frac{p^m}{CW_{\max}} & 2^{\lfloor \log_2 i \rfloor - 1} CW_{\min} + 1 \leq i \leq 2^{\lfloor \log_2 i \rfloor} CW_{\min} \\ \frac{p^m}{CW_{\max}} & 2^{m-1} CW_{\min} - 1 \leq i \leq CW_{\max} \end{cases} \quad (3)$$

where $\lfloor \cdot \rfloor$ is a function to round numbers, p is the probability of unsuccessful transmissions caused by the collision of the MAC layer and the channel fading of the physical layer, and α is times of backoff. Therefore, the expected value of backoff time is as follows.

$$\begin{aligned} \overline{BackoffTime} &= (1-p) \frac{CW_{\min}}{2} \\ &+ \dots + p^m(1-p) \frac{\sum_{i=0}^m 2^i CW_{\min}}{2} + \\ &\dots + p^{m_r} \frac{\sum_{i=0}^m 2^i CW_{\min} + (m_r - m) 2^m CW_{\min}}{2} \end{aligned} \quad (4)$$

For the periodic PIS service, the uplink is the CCTV, while the downlink is the PIS video stream. Packet sizes of PIS and CCTV are 20480 Bytes and 10240 Bytes, respectively. According to 802.11 MAC protocols, the maximum MPDU (MAC Protocol Data Unit) length is 4096 Bytes. As a result, the PIS frame and CCTV frame should be fragmented, and the maximum fragmentation of a MPDU is 3000 Bytes. A PIS frame could be divided into $\frac{VideoFrameLength}{3000 \times 8}$ fragments. According to the fragmented MPDU transmission procedure, the duration for a successful transmission of a PIS frame is calculated as follows:

$$T_{\text{video}} = \frac{L_v}{R} + (aSIFSTime + anACKTime) \times \lceil \frac{L_v}{l_m} \rceil \quad (5)$$

where R is the transmission rate, $anACKTime$ is the time for the transmitter to send an acknowledge frame, $\lceil \cdot \rceil$ is the top integral function, L_v is the length of a video frame, and l_m is the maximum length of MPDU stated in 802.11 protocols.

Based on the multi-matrices FSMC model in Wang et al. (2014), strength of interference signals could be obtained. As the receiver is equipped with a band-width filter, we could apply the filter's frequency response to calculate the leaked interference signal. Assume the filter's frequency response function is $F(f)$ and the power spectral density is $P(f)$. According to the channel spacing of 802.11g, the interference factor

can be derived as $IF = \frac{\int_{-\frac{w_a}{2}}^{\frac{w_a}{2}} P(f)F(f)df}{\int_{-\frac{w}{2}}^{\frac{w}{2}} P(f)df}$, where

w_a is the bandwidth of the adjacent channel and w is the bandwidth of the interference signal. Therefore, IF can be used to calculate the interference signal leaked into the adjacent channel based on the multi-matrices FSMC model.

Simulation Results and Discussions

Matlab is used to implement simulations, where there are 35 APs and the coverage of each AP is 500 m according to Wang et al. (2014). Figure 2a shows that the Q learning coverages about 600 iterations and packet loss rate decreases with the increase of learning times, which means optimal policies have been obtained. With the learning process being implemented, mean value of time latency is becoming lower and lower as shown in Fig. 2b, where it is about 5 ms when cognitive control converges to a stable state. Fig-

Interference Mitigation in Wireless Communications-Based Train Control (CBTC), Cognitive Control Approach, Fig. 2 Simulation results. (a) Packet losses versus learning steps. (b) Mean value of time latency

between consecutive instants of handoffs. (c) Handoff decisions under different policies. (d) Handoff latency under different policies

ure 2c demonstrates that cognitive control policies can almost eliminate the ping-pong handoffs. Besides, Fig. 2d shows that handoff latency under cognitive control policies is dozens of milliseconds, while handoff latency under traditional greedy policies is much higher close to 1 s.

the cognitive control approach can significantly reduce the packet losses, time delay, and handoff latency under interference from the coexisting PIS.

Conclusions and Future Work

Cognitive control is used to improve performance of CBTC train-ground communications under interference from co-existing PISs. Based on the cognitive control formulation, reinforcement learning was used to get the optimal strategy. Simulation results were presented to show that

Key Applications

The interference mitigation in wireless CBTC systems has been designed to increase the availability and reliability of train operation. The cognitive control based approach can real-timely make the interference mitigation decisions implemented on the physical layer, MAC layer and application layer.

Interference-Aware Distributed Resource Allocation

Hai Jiang

Synonyms

[Resource management](#); [Medium access control](#)

Definitions

Interference-aware distributed resource allocation refers to a distributed medium access scheme supporting multiple transmission links in a wireless ad hoc network, in which each

transmission link is aware of the interference level that it receives from other links.

Historical Background

A wireless ad hoc network is distributed in nature, and thus, a distributed medium access control (MAC) protocol is preferred. In the literature, the most popular distributed MAC protocols are based on carrier sense multiple access (CSMA) (Kleinrock and Tobagi 1975) or busy tone (Haas and Deng 2002; Wang and Zhuang 2006). In a CSMA-based MAC protocol, each sender first senses the wireless channel. If the channel is sensed free, the sender transmits its traffic to its receiver; otherwise, the sender defers its transmission. In a busy tone-based MAC protocol, when a sender is transmitting to its receiver, either the sender or its receiver sends a busy tone in another wireless band, to notify other potential senders. Other senders that hear the busy tone will defer their transmissions. It is challenging to guarantee quality of service (QoS) in a CSMA-based MAC protocol or a busy tone-based MAC protocol, due to the following reasons: First, both CSMA- and busy tone-based MAC protocols use channel contention. Second, mobility of the nodes makes it difficult to apply some QoS provisioning techniques such as reservation.

Key Applications

For a wireless ad hoc network, if the locations of the nodes are fixed (such as in a wireless mesh backbone), the work in Jiang et al. (2007) proposes a method to take advantage of the fixed locations of the nodes to improve the QoS, as follows.

The method is based on code division multiple access (CDMA), which allows concurrent transmissions for multiple sender-receiver pairs in a neighborhood. In the network, a common code is available for all nodes, and each node is also assigned with a unique transmitting code and a unique receiving code. As CDMA communica-

tions are interference-limited, one key issue is to make sure that the interference level at each receiver is under control such that the received signal-to-interference-plus-noise ratio (SINR) is not less than a predetermined threshold.

In the system, time is partitioned into slots. At the first portion of each slot, the receiver of each admitted communication link measures the interference level that it receives. At the remaining portion of each slot, if a node, say node i , wants to set up a communication link to its receiver denoted node j , node i first sends a probe message using the common code with a small power level (the purpose of the small power level is not to affect reception of existing links). By reception of the probe message, the receiver of an existing link can estimate the expected extra interference level it will experience if node i transmits its data traffic with normal power level. If the interference level is not tolerable, then the existing receiver sends a busy tone in another frequency band, which will notify node i not to transmit. If node i does not hear a busy tone, which means that all existing links are fine with node i 's transmission, node i sends a request to node j using node j 's receiving code. If node j has an acceptable SINR, it sends back an acknowledgement using its transmitting code to node i , which means that the link from node i to node j is admitted with resources reserved. In other words, node i can keep transmitting to node j by using its transmitting code with transmission quality guaranteed.

The advantages of the method are as follows: First, it is distributed, and thus, a central station is not needed. Only local observation of a node is needed for the node to decide whether or not its link can be admitted. Second, resource reservation can be achieved. Once a link is admitted, it does not need channel contention as in CSMA- or busy tone-based MAC protocols. Rather, the link admission means that QoS of all existing links and the new link can be guaranteed. Due to the fixed locations of the nodes, there is no "sudden" interference from moving nodes. Thus, all nodes can enjoy their target data transmission rates within their link durations. This also means low overhead, as the overhead only happens in the

link admission phase. Third, adaptive transmission rate can be achieved. Note that each receiver is aware of its received SINR. If the received SINR of a receiver is larger than its target SINR value, the receiver can notify its sender to transmit with a higher data rate by using variable spreading gain CDMA or multi-code CDMA. Fourth, each existing receiver estimates possible extra interference level from potential new transmissions. Thus, the interference awareness is receiver-centric. Compared to previous sender-centric schemes (Monks et al. 2001; Muqattash and Krunz 2003) in which each existing link notifies their neighbors of its tolerable interference level, the receiver-centric scheme does not need such notifications and thus, has much less overhead.

[TDMA link scheduling](#); [Wireless link scheduling](#)

Definitions

Interference-aware scheduling determines which links should transmit at which time slots so that all packets transmitted by the scheduled transmitters can be successfully received at receivers under wireless interference constraint. The successful reception of a transmission depends on several parameters, such as the transmission power, the received signal strength, and the interference caused by simultaneous transmissions. Thus, interference-aware scheduling has to consider interference models, traffic patterns, and network topologies. In addition, it is also often studied jointly with routing and power control. Interference-aware scheduling is one of the most fundamental problems for performance optimization in wireless networks.

Background

Wireless network systems have evolved with larger coverage area, higher user density, more diverse applications, and more aggressive usage of spectral resources. While spectral channels are reused for capacity improvement, interference among co-channel transmissions may also cause performance degradation, especially, in multihop wireless networks. One of the solutions is the scheduling of transmissions in a fair and efficient manner to avoid collisions (caused by interference). Such scheduling algorithm is

adopted at link layer in wireless networks as a part of medium access control protocol. Time-division multiple access (TDMA) is one of the most dominant access control solutions to achieve efficient interference-aware scheduling. In TDMA, time is divided into time slots, and a time slot is usually defined as the time unit to transmit a packet between two adjacent nodes. If two nearby transmissions occur simultaneously, collision of packet may happen at the receivers due to interference. TDMA scheduling aims to schedule such transmissions at different time slots to avoid collisions.

Scheduling algorithms in wireless networks have been studied for decades. Depending on the entity that is scheduled, there are node scheduling and link scheduling. In node scheduling, each node is scheduled to transmit at certain time slots, and each node's transmissions have to be received successfully by all its neighbors. In link scheduling, the transmission is intended between two endpoints of a link and have to be received successfully by the receiving node. Each link is scheduled for transmission at certain time slots to avoid interference. In this article, we only focus on wireless link scheduling (more specifically, TDMA link scheduling) in wireless networks. If the reader is interested in node scheduling, please refer to a nice survey by Gore and Karandikar (2011).

Interference-aware link scheduling algorithms have drawn significant attractions from both wireless networking and graph theory communities recently. There are numerous results obtained for various optimization problems under different interference models or network scenarios. Within this article, we briefly discuss the different models and classification methods of wireless link scheduling, summarize a few recent results, and then point out key applications of link scheduling.

Foundations

To perform interference-aware scheduling, first we need to understand the interference model which describe the effects of interference on the

operation of the network. Better characterization of interference can lead to better design of scheduling algorithm and better performance in real environment. There are mainly two interference models: *Protocol interference model* and *physical interference model*.

- *Protocol interference model*. In this model, a transmission by a node v_i is successfully received by a node v_j if and only if the intended destination v_j is sufficiently apart from the source of any other simultaneous transmission, i.e., $\|v_k - v_j\| \geq (1 + \eta)\|v_i - v_j\|$ for any node $v_k \neq v_i$. Here $\|v_i - v_j\|$ is the Euclidean distance between v_i and v_j , and constant $\eta > 0$ models situations where a guard zone is specified by the protocol to prevent a neighboring node from transmitting on the same channel at the same time. This model *implicitly* assumed that each node v_k will adopt the power control mechanism when it transmits signals. A variation of this model is introduced by Wang et al. (2006, 2008) with an assumption that each node v_k has its own fixed transmission power and thus a fixed transmission range t_k . In such model, each node v_k has an *interference range* r_k such that any node v_j will be interfered by the signal from v_k if $\|v_k - v_j\| \leq r_k$ and node v_k is sending signal to some node other than v_j . In other words, the transmission from v_i to v_j is viewed successful if $\|v_k - v_j\| > r_k$ for every node v_k transmitting in the same time slot using the same channel. Here $r_k > t_k$, and we usually assume that $\frac{r_k}{t_k}$ is bounded by a constant larger than one. Protocol interference model is the simplest communication model considering the interference among nodes; it does provide some good estimations of interference and enables a theoretical performance analysis of a number of protocols designed in the literature. However, it is sometimes too simple to capture the complexity of interference (such as the aggregate effect of interference).
- *Physical interference model* (also called *SINR Model*). In this model, node v_j can correctly receive the signal from the sender v_i if and

only if, given a constant $\eta > 0$, the signal-to-interference-plus-noise ratio (SINR) is

$$\frac{P_i \cdot \|v_i - v_j\|^{-\beta}}{N_0 + \sum_{k \in I} P_k \cdot \|v_k - v_j\|^{-\beta}} \geq \eta.$$

Here $\beta > 2$ is the path loss exponent, $N_0 > 0$ is the background Gaussian noise, I is the set of actively transmitting nodes when node v_i is transmitting, and P_i is transmission power of v_i . Note that the physical interference model is based on the power captured at the receiver and depends on the transmission power at all involved nodes. Thus, when we consider interference-aware link scheduling under this model, different power settings can lead to different problems. The common settings include uniform power setting (the transmission power is fixed at the same level for all nodes) or obvious power setting (the transmission power of a node is proportional to the link's path loss factor).

Comparing these two models, physical interference model considers the aggregate effect of interference at the receiver, due to other transmitters, while the protocol interference model focuses on the interference from nearby transmitters. Since the latter is much simple, it has been extensively adopted in the design and analysis of scheduling algorithms. Until recently, the physical interference model becomes more popular. There are also other types and variations of interference models; please refer to a nice survey on interference models (Cardieri 2010).

Besides the interference model, *network model* and *traffic model* are also important aspects to formally define the link scheduling problem. *Network model* includes: (1) What is the network topology (such as tree, mesh, arbitrary, or randomly distributed)? and (2) Does the network node have multiple channels or multiple radios (such as multiple-channel multiple-radio networks, cognitive radio networks)? The *Traffic model* describes the traffic patterns (where the traffics are injected to the network; Are they uniform?) and communication goals (such as

broadcast, point-to-point, multicast, and data collection). Various network/traffic models will change the link scheduling problem and lead to quite different solutions. For example, with multiple channels and multiple radios, the capacity of overall system can be significantly increased, but the search space for optimal scheduling is also enlarged. Scheduling for data collection in a sensor network may restrict the underlying topology to a data collection tree, where a link scheduling could be performed relevantly easily.

The link scheduling problem could have different optimization objectives, e.g., *throughput optimization*, *minimum scheduled length*, *minimum average delay*. For example, *shortest link scheduling* aims to find a link schedule of shortest length for a given subset of links, such that each link (a sender-receiver pair) is scheduled once. *Throughput optimization-based scheduling* (related to capacity problem or called single-slot scheduling) aims to find the maximum number of links that can communicate simultaneously. There are also other variations, e.g., weighted versions, fairness consideration, or under different communication scenarios. Most of these link scheduling optimization problems have been proved to be NP-hard; the majority of research works propose heuristics or approximation algorithms to find their solutions.

The proposed link scheduling algorithms can also be classified into *centralized* and *distributed*. *Centralized algorithms* have the global information of the network and solve the scheduling problem at a controller, while *distributed algorithms* perform the computing distributedly among the nodes, and each node may not have the global information. Usually centralized algorithms can achieve better performances. However, distributed algorithms are preferred at certain wireless networks, such as infrastructure-less multihop wireless networks.

Since there are so many different settings over various models, we would not be able to review all existing solutions for them. Here, we only briefly review a few recent results as examples. For more detailed review, please refer to the survey by Gore and Karandikar (2011).

Various TDMA link scheduling problem under *protocol interference models* have been well-studied, since it has a simple binary interference model. The conflict of transmissions on two distinct links is predetermined independently of the concurrent transmissions at other links. Therefore, the interference relationships can be modeled by a conflict graph, where there is an edge between two nodes (representing two links in the original communication graph) if and only if these two links are interfered to each other under protocol interference model. Then the link scheduling problem is converted to coloring problem on this conflict graph. Various graph theoretical approaches (such as classical greedy algorithm) can then be applied to find good solutions. For example, Wang et al. (2006) studied the TDMA link scheduling under fixed power protocol interference model. They proposed both centralized and distributed algorithms to schedule links over conflict graphs which use time slots within a constant factor of the optimum. Wan et al. (2011a, 2013) investigated wireless link scheduling to maximize concurrent multiframe in multiple-channel multiple-radio wireless networks under protocol interference model. Centralized approximation algorithms are proposed to achieve constant approximation, and both solutions leverage novel conflict graph construction and corresponding scheduling algorithms. Pan et al. (2012) considered link scheduling with cooperative communication in cognitive vehicular networks, where multiple bands and cooperative communication are used. They modeled the problem with a 3D cooperative conflict graph and proposed a heuristic pruning algorithm to solve the overall optimization problem.

The *Physical interference model* captures the aggregate effect of interference in the network; thus the interference at a receiver depends on all concurrent transmissions during that particular time slot, which makes it impossible to generate a conflict graph a priori. Therefore, previous graph coloring techniques based on conflict graphs become inapplicable, and designing scheduling algorithms under physical inter-

ference model becomes especially challenging. Recently, there are significant studies on link scheduling in the physical interference model. For example, Brar et al. (2006) considered the wireless link scheduling under physical interference model and proposed a heuristic algorithm, Greedy Physical, to provide feasible conflict-free scheduling. They also proved that it has an approximation factor if the network is uniformly distributed and every node has the same transmission power. Santi et al. (2009) considered link scheduling under a variation of physical interference model, called graded SINR model, which allows use of “imperfect links” with degraded performance. In addition to conflict-free constraint, the feasible link scheduling also requests the minimum quality of the usable links. Then a constant approximation algorithm (graded SINR) is given under graded SINR model. Blough et al. (2010) also investigated wireless link scheduling under physical interference model with uniform power settings and proposed the first constant approximation algorithm for physical interference model. Wan et al. (2011b) built a unified algorithmic framework based on a maximum independent set of links and developed a set of approximation algorithms for link scheduling with or without power control under physical interference model. Zhou et al. (2014) considered link scheduling to maximize the throughput under physical interference model and proposed the first localized algorithm that can achieve a constant fraction of the optimal capacity. Yu et al. (2016) also studied the distributed link scheduling algorithms with length-monotone sublinear power settings under physical interference model. For dense networks, their solution can achieve a constant approximation.

Besides considering link scheduling problem along, there are also many works combining it with other network issues, such as *routing* (Wang et al. 2008; Badia et al. 2008) and *power control* (Li and Ephremides 2005; Tang et al. 2006), to formulate the optimization problem. Usually, the joint optimization problems become harder to solve; therefore, more complex techniques such as linear programming are often used.

Key Applications

Interference-aware scheduling algorithms are fundamental in every multihop wireless network. They can be applied to improve the overall throughput, reduce packet delay, and increase system capacity. Besides the general multihop wireless networks, interference-aware link scheduling has been adopted in *wireless mesh networks* (Brar et al. 2006; Badia et al. 2008; Gore and Karandikar 2011) (possibly with multiple channels and multiple radios), *wireless sensor networks* (Chen et al. 2011, 2012; Chen and Wang 2012) (for data collection, aggregation, selection), and *vehicular networks* (Pan et al. 2012) (with high mobility, cognitive radio, cooperative communication, etc.).

IoMT Internet of Medical Things

Definition

The Internet of Medical Things (IoMT) is defined as a healthcare application of the Internet of Things (IoT) that enables the use of connected medical devices for sensing physiological data, storing medical information and/or records, and providing healthcare services by using sensor and actuator networks and the Internet.

Key Points

The IoT is a novel technology paradigm that has gained a huge interest in the field of wireless telecommunications in the last decade. The IoT is a network of things or physical objects that promises to connect hundreds of billions of things

or physical objects to the Internet (Jha 2018). The fundamental principle of the IoT is that things or physical objects, e.g., radio-frequency identification (RFID) tags; sensors and actuators of various types, sizes, and capabilities; data processing and storing elements; health-monitoring elements of the physical objects; intelligent decision-making and optimizing elements; computers and phones; etc., in the physical environment would use information and communications technologies to connect to each other and share information in order to achieve common goals. The idea of the IoT has been quite investigated in the last decade leading to potential applications for the emerging society (Al-Fuqaha et al. 2015; Atzori et al. 2010; Gubbi et al. 2013; Yin et al. 2018; Zanella et al. 2014; Li et al. 2018; Akmandor and Jha 2018; Yin et al. 2016; Russo and Eriksson 2018; He et al. 2018; Charlotte 2017; Coburn 2016; Marr 2018).

The IoMT is a major application area of the IoT targeted for the healthcare industry toward the smart healthcare paradigm. In the IoMT set-

ting, all the medical devices, ranging from stand-alone macroscale devices and equipment located at the hospitals and healthcare service providers, in-home medical devices and point-of-care units for remote point-of-care applications, and smart wearable devices (sensors, actuators, and communications devices) to mobile healthcare applications and biomedical implants, would potentially be connected to the Internet, which would provide services to personalized healthcare needs and hence a higher standard of patient care in the offered services by accessing medical information and healthcare big data (Meiling 2015). The IoMT paradigm has opened the door to a huge opportunity to receive healthcare services where the healthcare professionals and the patients could be at remote locations and thus realize remote point of care for elderly people and patients with limited mobility. Figure 1 shows a typical IoMT system where patients can be connected to healthcare service providers from patient homes or remote point-of-care as well as hospital rooms.

Internet of Medical Things, Fig. 1 A typical IoMT system

In general, the IoMT would possess similar structural elements as those of the IoT, namely, identification, sensing, communication, computation, services, and semantic elements (Al-Fuqaha et al. 2015). The key enabling technologies of the IoMT would be similar to those of the IoT, namely, identification tags and tag readers, e.g. RFID tags and readers, sensor networks, and a software layer, called the middleware, introduced between the technology and application levels (Atzori et al. 2010). Both wired and wireless communication systems and networks would be applicable to the IoMT framework. In addition to real-time access to IoMT data (information) clouds, all the data would be available to the healthcare service providers on non-real-time basis by accessing the medical data storage systems providing opportunities for post-analysis of physiological signals.

Biomedical implants and wearable medical devices would potentially play an important role in the IoMT because in the last decade their computational power, capacity, and networking capability have improved significantly, while their sizes have decreased opening the doors to smaller devices with enhanced performances (Yin et al. 2018). To this end, communication and networking among biomedical implants, from implants to on-body sensors (wearable devices) and from on-body wearable devices to stand-alone medical devices connected to the Internet, would open new research avenues within the IoMT area.

IoMT offers many benefits toward smart healthcare systems; however, major applications of the IoMT can be grouped into identification, authentication, and tracking of medical objects and people, sensing and monitoring of physiological signals, and collecting and storing of medical data and later sharing with appropriate parties when necessary (Atzori et al. 2010). The IoMT also provides opportunities for emerging medical applications, namely, remote monitoring of patients allowing for a significant cost saving by minimizing the number of hospital visits especially for the elderly patients, remote point of care at the patient locations, and remote surgery.

While the IoMT also offers other promises including better operational efficiency through technologically enhanced automation in health-care monitoring and access to medical big data, it may also bring along some risks associated with its technical implementation and medical data handling. For instance, security and privacy in medical data transfer and the consequences of network connection failures could be considered vital factors in the implementation of the IoMT in the near future.

Definition

IoT Forensic Science (IoTFS) is the use of digital forensic processes and procedures relating to the recovery of digital evidence originating from one of more IoT devices toward preserving, identifying, extracting, documenting, interpreting, and presenting digital evidence for the purpose of reconstructing IoT-related events. IoT-related events may reside across one or more configurable computing resources that are in close proximity to where an event has occurred (i.e., fog- or edge-based) or reside on distributed environments (i.e., private, public, or hybrid clouds). IoT forensic science extends that of digital forensics with main focus on the reconstruction of events involving one or more IoT devices to obtain a digital evidence.

IoT Digital Evidence (IoTDE) includes data or events that can be derived from a set of identifiable and configurable IoT objects including IoT devices, nodes, gateways, or cloud resources comprising of a variety of digital media including text files, digital multimedia files (e.g., audio, video, and images), databases, computer programs, hardware resources (e.g., hard disks, other disk drives, SIM cards, keystroke logger media, volatile memory).

Historical Background

Early generations of computers (between 1960s and 1980s) were primarily owned and operated by large corporations, universities, government agencies, and research centers (Sachowski 2019). The security of these systems was mainly the responsibility of system administrators managing the daily operations of these computers (Sachowski 2019). A number of government agencies including the US Department of Defense, US Internal Revenue Service (IRS), and Federal Bureau of Investigation (FBI) began forming ad hoc groups that volunteered to train case investigators on gathering information or extracting evidence from computer systems, mainly mainframe computers (Pollitt 2010). In 1976, Donn Parker, an information security researcher, introduced a book titled *Crime by Computer* describing approaches for using digital information to solve crimes that involved the use of computers.

With the introduction of personal computers (PCs) and as new technologies evolved, law enforcement agencies began introducing laws that address new forms of digital crimes. The Florida Computer Crimes Act was among the first computer-related crime laws introduced in 1978. Subsequently, other laws were introduced in response to the growing number of computer crimes including the US Federal Computer Fraud and Abuse Act (1984), an amendment of the Australian Crimes Act (1989) to include computer-related offenses, the British Computer Abuse Act (1990), among many others. In 1990, the International Association of Computer Investigative Specialists (IACIS) was formed which provided training services to computer forensics professionals around the world. In 1993, the Federal Bureau of Investigation (FBI) hosted the First International Conference on Computer Evidence. In 1995, the International Organization on Computer Evidence (IOCE) was formed.

A number of forensic tools that targeted specific forensic problems were introduced in early 1990s including Gord Hama's RCMP Utilities, and Steve Choy's IACIS Utilities,

among many others. One of the first known commercial computer forensics program that was used by many law enforcement agencies globally was SafeBack, a DOS-based utility program that primarily focused on creating and restoring images of hard disks of Intel-based computer systems (Stephenson and Gilbert 1999). Throughout the 1990s, more advanced forensic tools were introduced such as the EnCase and Forensic ToolKit (FTK), two of the most popular forensic tools. As computing devices and Internet became more ubiquitous, the area of digital forensics witnessed significant growth in size and breadth.

In 2001, the Digital Forensics Research Workshop (DFRWS) was first held and the term digital forensics was introduced (Palmer 2001). The DFRWS also proposed a set of principles that relate to digital evidence including: (a) identification, (b) preservation, (c) collection, (d) examination, (e) analysis, and (f) presentation (Palmer 2001). In 2006, the United States Courts adopted digital information as a new form of evidence implementing a system called electronic discovery for dealing with digital evidence (Civil Litigation Management Manual 2010). In 2014, the National Institute of Standards and Technology (NIST) Cloud Computing Forensic Science Working Group was formed to discuss the forensic challenges in the cloud computing paradigm (NIST 2014).

In recent years, the Internet of Things (IoT) has become a ubiquitous technology due to the proliferation of powerful IoT devices that can perform a variety of tasks. This emerging paradigm, however, has introduced new challenges in dealing with digital evidence for cases where committed crimes involve the use of IoT devices deployed on local (i.e., fog- or edge-based) or cloud (private, public, or hybrid) environments.

Foundations

Digital forensics is a process that encompasses the acquisition and analysis of any forms of digital artifacts on digital devices which can be

used by forensic investigators as digital evidence. NIST defines digital forensics as “the application of science to the identification, collection, examination, and analysis, of data while preserving the integrity of the information and maintaining a strict chain of custody for the data” (Kent et al. 2006).

A digital forensic investigation (DFI) can be defined as a process that determines and correlate information extracted from a digital evidence for the purpose of establishing factual information that can be used for judicial reviews (McKemmish 1999; Jeong 2006). Traditionally, digital forensic investigations follow a reactive approach in which an investigation is typically conducted to solve a digital crime that has been committed.

Digital evidence comprises of data that resides on computing or mobile devices including, but not limited to, data files, text messages, audio, video, or images. Data associated within a running software or hardware can also be part of a digital evidence. A digital evidence is typically obtained when solving crimes that involve the use of digital artifacts as part of a DFI. Digital forensic investigators use DFI tools and techniques for the purpose of collecting digital evidence that can further be used for reporting during the investigation of crimes that involve the use of digital media.

Furthermore, digital forensic investigators gather and analyze all crime-related digital evidence to draw conclusions about a suspect and devise a coherent sketch or plan of how a crime has been committed. To this extent, investigators use a wide variety of forensic tools to help them create case files for recording all case-specific evidence (e.g., blood samples, fluid, fingerprints, hard drives, and computing devices, among others).

Edmond Locard, one of the pioneers in forensic science, introduced what is known as *Locard Exchange Principle* which states that any contact a person makes with another person, place, or object results in the exchange of physical materials (Chisum and Turvey 2000). In the case of IoT, this principle may still apply. For example, if a suspect attempts to control an IoT device, the exchange of physical materials or evidence

in this case are the data files logging activities that can provide tracing information or clues. However, IoT system attacks may involve remote control in which the suspect may not be present in close proximity of IoT devices being controlled. Hence, the exchange of physical materials in such cases can be limited to only software interactions involving digital, network, or storage media where a physical interaction that can be used as evidence is nonexistent.

Key Applications

There are a number of branches of digital forensic science that span across a variety of disciplines. That is, digital evidence can be extracted from a number of different types of digital devices (e.g., laptops, mobile devices, and hard disks, among many others) that may be deployed across multiple different network environments (e.g., private, public, and hybrid). In forensic science, forensic methodologies that are applied for the gathering of information as part of a forensic investigation are not merely restricted to computing devices and involve other disciplines such as accounting, toxicology, odontology, pathology, psychology, archaeology, and dentistry among many others. The following subsections describe the areas in which digital forensic science is applied with primarily focus on the digital forensic investigation types or branches that involve forensic techniques used to gather evidence from electronic or digital artifacts.

- *Computer forensics* relates to the identification, preservation, collection, analysis, and reporting of digital evidence that can be discovered on computing devices such as computers, laptops, tablets, or storage media (Kruse and Heiser 2001). Examples of storage media include, but not limited to, hard disks, other disk drives, USB drives, BIOS information, and an operating system’s registry hives, among others.
- *Mobile forensics* relates to cases involving mobile device technology (Reiber 2016)

(e.g., mobile phones, game consoles, and GPS devices, among others) where evidence that can be recovered for the purpose of information gathering involves digital artifacts on a mobile device. Examples of digital artifacts include, but not limited to, SIM card, images, documents, contact lists, configuration files, and mobile network information, among others.

- *Network forensics* deals with gathering digital evidence through network traffic (Messier 2016). This process involves monitoring, capturing, storing, and analyzing network traffic for collecting digital evidence or intrusion detection. An example of network-related evidence is network traffic filtration which ensures only authorized users can gain access to parts of a desired network.
- *Memory forensics*, also known as *live forensics or acquisition*, deals with recovering evidence from a live setting involving the gathering, capturing, and analyzing of volatile data where evidence is lost when a device or system is powered off (Ligh et al. 2014). Volatile data may reside, for example, on random access memory (RAM) or as data travels through a network channel.
- *Electronic discovery or e-discovery* is a reporting technique that facilitates an investigation in which gathered information is obtained as electronically stored information (ESI) for the purpose of supporting government investigations or a litigation (Phillips et al. 2013). Examples of e-discovery ESI include, but not limited to, identification of documents, preserving data relevant to an investigation, transferring data to legal counsel, and extracting text or metadata from native documents.
- *Database forensics* deals with the recovery of digital evidence involving the use of databases (Adedayo and Olivier 2014) or a database management system (DBMS). Database forensics is required in scenarios such as database failure, deleting persistent data, and detecting suspicious behavior in using the database, among others. Examples involving the use of database forensics include, but not

limited to, fragmented data, stored metadata, or page information reconstruction.

- *Cloud forensics* deals with the recovery of digital evidence involving a cloud computing resource (NIST 2014). The process includes identifying, gathering, preserving, and reporting elements of a digital evidence that may reside across distributed environments. Cloud forensics is an extension of the network forensics. An example that involves the use of cloud forensics is the process of reconstructing a cloud-based event across a cloud-computing environment.
- *IoT forensics* is an all-encompassing forensic type that utilizes many of the other forensic approaches. IoT forensics deals with the recovery of digital evidence from IoT devices. The process includes identifying, gathering, capturing, preserving, and reporting elements of a digital evidence that may reside across shared pool of computing resources and which reside locally (fog- or edge-based) or on distributed environments (cloud). An example that involves the use of IoT forensics is reconstructing IoT-based events that have occurred within IoT systems (e.g., unauthorized access to control an ultrasonic IoT sensor). IoT forensics is an extension of cloud forensics.

IoT Devices and Digital Artifacts

Over the past few years, digital technologies have played a major role in producing various digital forms of artifacts containing information that can be used or shared over the Internet. As we rely on using digital technologies for the dissemination and processing of information, new challenges and trends in digital crimes are emerging.

There are numerous synonyms that are used interchangeably for the distinct role played by digital technologies relating to crimes such as cybercrime, digital crime, e-crime, computer crime, and high-tech crime, among many others. Donn Parker (1998) studied the various types of crimes that employ computers and categorized them into four different roles: (a) object of crime, (b) subject of crime, (c) tool of crime, and (d)

Internet of Things (IoT) Forensic Science, Table 1 Relating Donn Parker Categorization to the Internet of Things (IoT)

Category	Example of a baby-monitoring IoT system
Object	An Internet-connected baby monitoring device is damaged
Subject	Monitoring device camera is infected with malware (e.g., Mirai)
Tool	Use IoT device to carry a DDoS attack causing outages via cloud infrastructure
Symbol	Attacker uses baby monitoring device to threaten or intimidate users of system

symbol of crime. Although these categories were identified in the 1970s, they are still applicable today across many areas including IoT as presented in Table 1.

However, the categories identified by Donn Parker (1998) do not consider the differences between the type of component that can be an object, subject, tool, or symbol. In some cases, for example, the computing device hardware can be considered as a contraband, instrumentality of crime, or evidence of crime, whereas this hardware serves as a medium for storing files that are themselves contraband, instrumentalities of crime, or evidence of crime (Jarrett and Bailie 2015).

With the increasing number of IoT devices, the need for effective digital forensic techniques that can be tailored to IoT systems for solving computer-related crimes becomes inevitable. Traditionally, digital forensic techniques and tools have been dependent file systems to forensically extract digital evidence, recover data, or reconstruct events. Such techniques are no longer be applicable or effective in the IoT paradigm (Al-Masri et al. 2018).

IoT Forensics

An IoT system typically employs a cloud platform for the deployment and management of IoT services or applications running on remote, virtualized environments that are managed by third party cloud providers. This deployment model poses serious implications on how digital evidence can be obtained. In addition, post-event response activities such as gathering and processing digital evidence generally occur after an incident or a digital crime is committed. As

the number of IoT devices proliferate, applying this reactive process of digital forensics becomes increasingly inadequate. It would be desirable to employ a proactive process such that gathering and preserving digital evidence is transpired prior to the occurrence of an accident. This can be achieved by equipping an IoT system to be forensic ready.

At the core of an IoT system is a device layer that provides the basic functional capabilities such as sensing and actuating. Through this layer, IoT devices can collect, process, or exchange data. In order to perform any of these tasks, an IoT device need to be equipped with sufficient capabilities embedded within the device itself including, for example, computational capability, sensing or actuating, power source, and connectivity, among others. However, IoT devices vary in the degree to which they offer these capabilities. In addition, IoT devices may not be virtually accessible which makes the task of collecting information that can be used as digital evidence challenging.

Furthermore, digital forensic techniques for many years have primarily focused on content and relied on the gathering and tracing of information without considering the context in which devices were used in a malicious attack (Al-Masri et al. 2018). Due to the fact that IoT devices are typically constrained in terms of storage and computational capabilities, it is a very common task that data is overwritten occasionally. In addition, IoT systems consist of heterogeneous devices that vary in terms of hardware types as well as identification, sensing, and communication capabilities. This makes the task for recovering data or collecting digital forensic evidence more challenging. Listed below are some of the key characteristics that require

addressing when considering IoT forensics and dealing with digital evidence involving IoT devices.

- *Aggregation*: IoT services are generally deployed across a distributed network. The ability to reconstruct events that may be disseminated through a number of virtual resources to be used for digital evidence is time consuming and complex.
- *Accessibility*: Gaining access to forensic evidence in cloud environments involves IoT service providers who may be reluctant to share data or enable investigators to perform information gathering.
- *Availability*: In the event a breach occurs within an IoT system, some services may be interrupted or network may become unavailable.
- *Deployment*: The process of acquiring IoT digital evidence varies based on the type of environment in which the IoT system is running. For example, processing or collecting evidence varies when an IoT system is deployed on an Infrastructure-as-a-Service (IaaS) or Platform-as-a-Service (PaaS).
- *Documentation*: The heterogeneity in device types is common in IoT systems which makes the process of documenting digital evidence a very complex task and requires extensive domain knowledge across many technologies and protocols.
- *Confidentiality*: IoT systems may have services or applications deployed on the cloud or fog gateways. This increases the risk of data becoming compromised due to the fact that multiple entities or devices may be involved. In addition, multi-tenancy increases the risk of breaching data confidentiality due to data remanence in IoT environments.
- *Integrity*: IoT systems that reside in multi-tenant environment such that data may be shared by many computing devices in a distributed environment can cause digital evidence to be altered without the ability of accurately tracing information.
- *Nonrepudiation*: IoT devices have limited computational capabilities which constrain

their ability to question, repudiate, or deny a traceable message that may have changed by a malicious attack.

- *Preservation*: In cases cloud service providers provide investigators access to IoT services, an attacker may purposefully remove or destroy tracing information.
- *Privacy*: IoT systems depend on the use of services to execute specific tasks through resource URIs (as in the case of REST). In such cases, a URI may expose private metadata thus breaching confidentiality and privacy as well as it may allow malicious entities to infer some information about an IoT device. For an example, assume a REST service URI with the address `http://myHouse/basement/myOffice/light/1` is used to control the status of a light device that is part of a smart home system. Using this URI, a malicious entity may acknowledge that using a HTTP post request to the device translates into turning on the light in the office located in the basement of a tenant's house. The loss of privacy and confidentiality makes the task of reconstructing events or identifying digital evidence a very complex process.
- *Provisioning*: IoT services' provisioning require elasticity which can scale up or down, thus releasing some capabilities which can cause digital evidence to be changed or an event to be lost during evidence collection.
- *Qualifications*: Certain digital forensic techniques may not be relevant to IoT forensics. Therefore, an investigator needs to have sufficient qualifications and expertise when collecting digital evidence involving an IoT system.
- *Trustworthiness*: It is possible that an IoT device or node gets tampered with, stolen, or loses connectivity within an IoT system. The ability to track devices in such situations is nearly impossible.
- *Tracking*: Prior to information gathering by a digital investigator, there is no guarantee with respect to an investigator being the first person on the scene to collect data (e.g., first responder).

- *Size*: The miniaturization of IoT devices limits their capabilities and as a result these devices may not be equipped with fault-tolerant mechanisms in case of malfunctioning.

Future Directions

Digital forensics that involve IoT systems or IoT devices is in the infancy stage. IoT forensics need to transcend the acquisition of data stored locally on hardware resources which can be used for performing detailed analysis or examination of traffic logs. The fact that IoT devices may not be easily reachable or virtually accessible over the Internet requires more adaptive digital forensic techniques that automate some of the basic digital forensic functions. In addition, generated and stored data play a critical role in the acquisition of digital evidence for IoT systems. Therefore, an IoT forensic model needs to maximize the potential use of digital evidence while minimizing costs associated with forensic investigations (Sachowski 2019).

Maintaining and preserving electronically stored information (ESI) that can be used by an IoT system for the purpose of recording users' activities or interactions are of critical importance to IoT forensics. Examples of such records include authentication records, event logs, error logs, transactional records, database records, registry hives, security logs, and configuration files, among many others. Furthermore, applying automatic machine learning and artificial intelligence algorithms that can identify suspicious activities across any ESI along with other background evidence (e.g., authentication records, network device logs) would render automatic forensic processes and facilitate automatic detection of abnormalities.

It is imperative that IoT systems are equipped with the tools necessary to prepare for the need of information gathering for digital evidence. To this extent, it is of great importance that an organization considers formalized plans which identify key goals that affect digital evidence through a set of useful policies and guidelines. These policies and guidelines will help in creating a framework

that can be used to achieve a high-level of digital forensic readiness.

Digital forensic investigations are generally performed as a response to an incident that involves a digital crime. This technique may not be useful for IoT forensics. Information gathering for a digital evidence must be performed in real-time or detected in advance. To this extent, IoT systems must be designed such that they are digital forensics ready. IoT forensics readiness means that an IoT system has the ability to preemptively exploit electronically stored information for the purpose of collecting credible or admissible digital evidence when signs of a digital crime are evolving or as the residual risks associated with an incident increase. This will enable IoT systems increase the potential use of digital evidence whereas organizations will be able to mitigate the impact of risks proactively while reducing investigative costs.

In order to achieve IoT forensic readiness, a number of practices should be discussed. Listed below are some of the practices or procedures that should be considered by organizations for supporting IoT forensics readiness when developing IoT systems.

- Identify business risks clearly and associate a ranking priority to each risk (higher priority indicates high risk).
- Identify all IoT data sources at the local (e.g., fog- or edge-based) and cloud (e.g., public, private, and hybrid) levels and associate an integrity ranking priority to each data source.
- Associate the risks with identified IoT data sources.
- Document the process involved in information gathering for an IoT digital evidence from IoT devices.
- Develop supporting capabilities that enable the automatic detection of incidents and gathering of digital evidence as incidents evolve. This can be achieved by equipping the system to automatically detect anomalies in data streams or event records through the use of machine learning or artificial intelligence techniques.

- Establish a strategy for detecting and collecting credible or admissible digital evidence.
- Identify the process associated with formalizing digital investigations as a result of detecting incidents, suspicious events, or abnormalities in sensory data streams.
- Establish a strategy for deterring incident events which can be achieved using fault-tolerance techniques.
- Establish a framework for presenting credible evidence based on factual information.

In digital forensic investigations, establishing a framework for identifying and maintaining a credible or admissible digital evidence is critical for yielding accurate conclusions based on factual information. IoT forensics is an all-encompassing apparatus that uses forensic approaches spanning across a number of areas including cloud, computers, database, network, and mobile, among many others. IoT forensics deals with reconstructing events and the recovery of digital evidence involving the use of IoT devices. The proliferation and heterogeneity of IoT devices increase the need for organizations to employ processes, procedures, training, and tools that are specifically designed for digital forensics involving IoT devices while ensuring reliability when drawing conclusions as part of a digital investigation. The growing number of IoT devices also increases the need for organizations to collaborate at a level that supports the interoperability of the processes or procedures applied in IoT forensic investigations.

Internet of Things for Vessels

► Maritime Internet of Vessels

Internet of Things: Architecture, Key Applications, and Security Impacts

Hansong Xu, Fan Liang, and Wei Yu
Department of Computer Engineering, Towson
University, Towson, MD, USA

Introduction

Thanks to recent advances in Internet of Things (IoT) technologies (Lin et al. 2017; Stankovic 2014; Yu et al. 2018), a number of IoT-based systems, including the smart grid, smart transportation, and smart manufacturing, among others, can be supported (Catarinucci et al. 2015; Lin et al. 2015; Wu et al. 2017; Xu et al. 2017a,b, 2018a,b). With IoT, timely monitoring and controlling of physical components via deployment of both sensing and actuating devices can be enabled. Such a feedback loop for monitoring and control can improve the efficiency of power management, travel planning, and manufacturing production, to name just a few. For example, in the smart grid, physical components (power plants, transmission lines, substations, appliances, etc.) can be monitored and controlled, leading to two-way communication of both power and information flows. Smart meters, as typical sensing devices, can detect the demands from consumers and the state of both traditional energy generators and renewable energy resources and transmit sensed information to the operation center. Based on collected sensing information, the operation center can coordinate the energy supply in supporting the demand variation. In this way, efficient and resilient energy management can be realized in the smart grid.

In the smart transportation system, IoT technologies enable the interconnection of vehicles, roadside units (RSUs), and drivers to improve travel efficiency and safety (Lin et al. 2015; Xu et al. 2017b). For instance, traffic information, which is collected and shared among vehicles, can be used to derive optimal routes for drivers. In addition, emergency safety events (collisions, breakdowns, etc.) during travel can be broadcasted to nearby vehicles to alert drivers or to ask for assistance. Similarly, smart manufacturing is envisioned as the next revolution in the manufacturing industry (Davis et al. 2012; Kang et al. 2016; Kusiak 2017; Xu et al. 2018a). In the smart manufacturing system, IoT integrates system automation, intelligent control, and distributed sensing in all appropriate stages of the manufacturing processes within a factory or plant to optimize resource efficiency and productivity (Lu et al. 2016). As an example, in monitoring of the supply chain along with a local manufacturing process, the optimal production efficiency can be achieved through seamless information collection and dissemination among activities, as well as across the supply chain, including raw material management, logistics, production and consumption, and others.

With the massive deployment of smart sensors and actuators, excessive and valuable data is collected, processed, and shared, making IoT-based systems attractive targets for curious and malicious adversaries. Moreover, IoT-based systems suffer vulnerabilities from the perspectives of software, hardware, communication protocols, and so on, which can be leveraged by adversaries to launch attacks. Cyber-attacks on IoT-based systems can be categorized by their impacts on the three-layer architecture (i.e., perception layer, network layer, and application layer). By exploring cyber-attacks on IoT-based systems, the impacts on smart grid, smart transportation, and smart manufacturing can be further investigated. To design effective defensive schemes, the vulnerabilities shall be investigated first, and then the corresponding defensive schemes shall be examined by considering the nature of IoT-based systems and the impact of the attack. Also, the defensive schemes

must be evaluated comprehensively before wide deployment.

In this entry, we make the following contributions:

- We present the smart grid, smart transportation, and smart manufacturing as three key IoT-based systems from the perspective of a three-layer IoT architecture (i.e., perception layer, network layer, and application layer). In the IoT architecture, the perception layer consists of diverse things, the network layer includes a variety of networks and related technologies, and the application layer provides diverse services for IoT-based systems. We also present the information flows that show the data collection and control command dissemination for the three representative IoT-based systems.
- We design a taxonomy to investigate cyber-attacks on IoT-based systems and their impacts from the perspective of the three-layer system architecture. Particularly, in the perception layer, cyber-attacks (e.g., node capture attacks, malicious code injection attacks, and false data injection attacks, among others) are investigated, as well as their impacts, including data tampering, device tampering, and device authentication disruption. Cyber-attacks (denial-of-service (DoS) attacks, spoofing attacks, sinkhole attacks, and wormhole attacks, among others) are considered in the network layer, as well as their impacts (service disruptions, disrupting device authentication, stealing sensitive data, etc.). In the application layer, phishing attacks, malicious worms/virus, and malicious scripts are considered, as well as their impacts such as stealing sensitive data and damage to the system.
- We conduct a case study on the investigation of data integrity attacks and the design of defensive schemes for the smart grid. We also discuss some open issues, including the investigation of cyber-attack risks on IoT-based systems, the design of defensive schemes, and the development of integrated evaluation platforms.

The remainder of the entry is organized as follows: In section “[Overview of IoT](#)”, we present an overview of IoT. In section “[A Taxonomy of Cyber-Attacks on IoT-Based Systems](#)”, we present cyber-attacks on some representative IoT-based systems from the perspective of the three-layer architecture (i.e., perception layer, network layer, and application layer). In section “[Case Study](#)”, we present a case study of cyber-attacks on IoT-based systems, such as data integrity attacks on the smart grid. In section “[Future Directions](#)”, we discuss some open issues from risk assessment, defensive schemes, and evaluation platforms. Finally, we conclude the entry in section “[Final Remarks](#)”.

Overview of IoT

In this section, we first introduce a three-layer IoT architecture and several representative IoT-based systems. We then show how the information flows within the system and introduce the corresponding deployment scenarios for the three representative IoT-based systems.

IoT Architecture and Applications

We can generalize IoT architecture into three primary layers, including the perception layer, network layer, and application layer, as shown in Fig. 1 (Lin et al. 2017). The perception layer integrates things (computing and network-connected devices) in IoT-based systems by direct perception and collection of data associated with the physical objects. The perception layer plays an important role in connecting those things to IoT networks. The network layer consists of a number of IoT networks and related technologies, including wireless sensor network (WSN), wireless sensor and actuator network (WSAN), next generation wireless networks, and so on. After being integrated into the network layer, those IoT networks deliver high volumes of widespread perception data to corresponding recipients. Supported by the network and perception layers, the application layer provides services (e.g., storage, analytics) with the aid of cloud and edge computing infrastructures and machine learning

Internet of Things: Architecture, Key Applications, and Security Impacts, Fig. 1 A three-layer architecture for I-IoT

technologies (Yu et al. 2018; Hatcher and Yu 2018). The smart grid, smart transportation, and smart manufacturing are typical examples of IoT-based systems.

As shown in Fig. 1, the smart grid, smart transportation, and smart manufacturing are based on a vertical architecture. Particularly, the smart grid system integrates cyber-components (i.e., sensing, computation, and communication) in power generation, transmission, and utilization of the physical power grid system, to improve its intelligence and efficiency (Xu et al. 2017a). Similarly, the smart transportation system enables traffic information collection, analysis, and sharing among massively deployed vehicles, RSUs, and travelers, to improve travel management and driving safety (Lin et al. 2015; Xu et al. 2017b). The smart manufacturing system interconnects diverse and multitudinous manufacturing things, including sensors, actuators, controllers, robotic arms, and production lines, among others, to improve productivity and resource efficiency (Xu et al. 2018a). Those IoT-based systems can be generalized as the seamless integration of cyber-components with traditional physical

components from a cyber-physical perspective. In addition to the aforementioned systems, there are many other IoT-based systems, including smart healthcare, smart cities, and smart homes, to name a few.

Feedback Loop Information Flow

We now present the information flow and corresponding deployment scenarios for the aforementioned IoT-based systems in Fig. 2. Generally speaking, in the perception layer, things collect data and push the data upward to the computing operation centers. Then, the computing center leverages powerful computing and analytic tools to process and analyze data and derive optimal decisions. Finally, the center disseminates corresponding control commands and messages to the things (as actuators) in closed-loop.

This closed-loop information flow is generic and can be applied to numerous IoT-based systems. For example, Fig. 2a illustrates an automatic metering scenario in the smart grid. The smart meters collect energy usage data from residential buildings and transmit the data to the corresponding computing operation

Internet of Things: Architecture, Key Applications, and Security Impacts, Fig. 2 Information flow and deployment scenarios for (a) smart grid, (b) smart transportation, and (c) smart manufacturing

center. Figure 2b presents a scenario in which vehicles and RSUs are interconnected for information sharing (e.g., emergency message broadcasting). The traffic information can also be collected and pushed to the computing operation center for optimized traffic management. Figure 2c illustrates a scenario related to sensing and actuation for smart manufacturing. The information can flow among the sensors, controllers, and actuators locally or via the computing operation center when computation-intensive tasks are carried out.

A Taxonomy of Cyber-Attacks on IoT-Based Systems

Based on the layered structure of IoT-based systems and the information flow illustrated in section “Overview of IoT”, massively deployed IoT devices continuously generate and transmit valuable information to support the efficient and resilient operations of physical systems. Nonetheless, this makes IoT-based systems attractive attack targets for adversaries, raising significant security challenges. From

the perspective of the layered architecture, the different security challenges between layers have garnered significant attention from the research community. For example, Lin et al. (2017) investigated cyber-attacks on IoT-based systems from the perspective of the three layers. Node capture attacks, malicious code injection attacks, false data injection attacks, replay attacks, cryptanalysis and side-channel attacks, eavesdropping and interference attacks, and sleep deprivation attacks are considered as representative cyber-attacks in the perception layer. Denial-of-service (DoS) attacks, spoofing attacks, sinkhole attacks, wormhole attacks, man-in-the-middle (MITM) attacks, routing information, Sybil attacks, and unauthorized access are likewise grouped into representative cyber-attacks in the network layer. In addition, the examples of cyber-attacks in the application layer include phishing attacks, malicious worms/virus, and malicious scripts, among others. To understand those cyber-attacks, we investigate the impacts of cyber-attacks on different IoT-based systems in the perception layer, network layer, and application layer in detail.

Cyber-Attacks in Perception Layer

We use Table 1 to illustrate the aforementioned cyber-attacks in the perception layer on the smart grid, smart transportation, and smart manufacturing, as well as their impacts. To be specific, we describe the consequences of node capture attacks (A_1), malicious code injection attacks (A_2), false data injection attacks (A_3), replay attacks (A_4), cryptanalysis and side-channel attacks (A_5), eavesdropping and interference attacks (A_6), and sleep deprivation attacks (A_7) on the smart grid, smart transportation, and smart manufacturing. In addition, we classify those cyber-attacks by their impacts, including data tampering, device tampering, disrupting device authentication, stealing sensitive data, and causing damage.

Regarding node capture attacks (A_1), the adversary could capture, tamper with, and redeploy devices to further gain control over other IoT devices, monitor the system, or introduce incorrect information to the system.

For example, the adversary can first modify smart meters and redeploy them in the smart grid, and then use the compromised smart meters to report false metering data to steal electricity. In addition, the manipulation of a large number compromised smart meters can cause severe economic losses to the system. Similarly, in the smart transportation system, the compromised vehicles could report incorrect traffic status information, which could cause inefficient route management (Lin et al. 2018). An aggressive adversary could use a large volume of compromised vehicles and RSUs to maximize the damage to the transportation infrastructure.

As another example, to launch a false data injection attack (A_3), adversaries inject false data in place of legitimate measurement data to mislead management mechanisms and disrupt power generation, distribution, and utilization. Particularly, the false data injected in the smart grid could maliciously affect a number of critical functions, such as state estimation (Yang et al.

Internet of Things: Architecture, Key Applications, and Security Impacts, Table 1 Cyber-attacks in perception layer and impacts

Attacks in perception layer	Smart grid (Recall Fig. 2a)	Smart transportation (Recall Fig. 2b)	Smart manufacturing (Recall Fig. 2c)
Node capture attacks (A_1) <i>Data tampering</i>	Compromised smart meters report false meter readings	Compromised vehicles or RSUs report false measurement data	Compromised sensors or controllers report false measurement data or false control commands
Malicious code injection attacks (A_2) <i>Device tampering</i>	Adversaries inject malicious code to smart meters to perform illegitimate functions	Adversaries inject malicious code to vehicles or RSUs to conduct illegitimate activities	Adversaries inject malicious code to sensors or controllers to modify control logics
False data injection attacks (A_3) <i>Data tampering</i>	Adversaries inject false data (e.g., meter reading) to steal electricity	Adversaries inject false data (e.g., traffic status) to disrupt traffic management	Adversaries inject false data (e.g., control parameters) to alter control objectives
Replay attacks (A_4) <i>Disrupt device authentication</i>	Grant trust to malicious meters	Grant trust to malicious vehicles or RSUs	Grant trust to malicious sensors, actuators, or controllers
Cryptanalysis attacks and side-channel attacks (A_5) <i>Disrupt device authentication</i>	Adversaries can leverage side-channel information to disrupt the authentication functions	Adversaries disrupt the authentication of vehicles to vehicle and vehicle to RSU	Adversaries disrupt the authentication of manufacturing devices (e.g., robotic arms, machines)
Eavesdropping and interference attacks (A_6) <i>Stole sensitive data</i>	Legitimate data can be stolen by adversaries via eavesdropping	Adversaries eavesdrop sensitive data (e.g., route, destination, identification)	Adversaries eavesdrop sensitive data (e.g., control parameters, productivity)
Sleep deprivation attacks (A_7) <i>Cause damages</i>	Adversaries disrupt the sleep cycle of smart meters	Adversaries disrupt the sleep cycle of RSUs	Adversaries disrupt the sleep cycle of sensors, actuators, and controllers

2014), energy pricing (Lin et al. 2016), and renewable energy resource integration (Lin et al. 2012), among others. In the case of the smart manufacturing system, false data injection attacks can cause severe impacts on manufacturing plants and factories. The input of false data in the closed-loop control system could generate misleading control signals, which negatively impacts production quality, cause damage to manufacturing equipment, and even endanger the safety of workers and the work environment.

Cyber-Attacks in Network Layer

Table 2 illustrates some examples of network-layer cyber-attacks on the smart grid, smart transportation, and smart manufacturing, including DoS attacks (A_8), spoofing attacks (A_9), sinkhole attacks (A_{10}), wormhole attacks

(A_{11}), man-in-the-middle (MITM) attacks (A_{12}), routing information attacks (A_{13}), Sybil attacks (A_{14}), and unauthorized access (A_{15}), as well as their impacts.

For example, the adversary launches DoS attacks to consume all resources for manufacturing control and management. Once successful, the DoS attacks result in the unavailability of critical control services, including process control, product inspection, and so on, greatly hindering or disabling services in the smart manufacturing system. In addition, DoS attacks on the smart grid and smart transportation system could result in the dysfunction of critical services, including power generation, transportation utilization, and pricing, as well as traffic management, location-based services, and driving safety. Moreover, in a large-scale

Internet of Things: Architecture, Key Applications, and Security Impacts, Table 2 Cyber-attacks in network layer and impacts

Attacks in network layer	Smart grid (Recall Fig. 2a)	Smart transportation (Recall Fig. 2b)	Smart manufacturing (Recall Fig. 2c)
DoS attacks (A_8) <i>Service Disruptions</i>	Make IoT system resources unavailable to legitimate requests	Adversaries bombard IoT network, leading to failure on delivery of time-critical tasks from vehicles or RSUs	Adversaries disrupt the timely delivery of time-sensitive control data in control loops
Spoofing attacks (A_9) <i>Disrupt device authentication</i>	The malicious meters could be admitted into the smart grid system	Adversaries use malicious devices to affect the smart transportation system	Malicious devices affect the normal operation of control loops in the smart manufacturing system
Sinkhole attacks (A_{11}) <i>Steal sensitive data</i>	Adversaries can collect a large amount of legitimate smart meter data	Massive sensitive and private vehicle and traffic information can be disclosed	Adversaries can steal sensitive and valuable manufacturing data
Wormhole attacks (A_{10}) <i>Steal sensitive data</i>	Same as A_9	Same as A_9	Same as A_9
MITM attacks (A_{12}) <i>Steal sensitive data</i>	Adversaries can collect and alter legitimate smart meter data via malicious devices	Adversaries can obtain and alter sensitive traffic and vehicle data	Adversaries can obtain and alter sensitive and valuable manufacturing data
Routing information attacks (A_{13}) <i>Cause damages</i>	Disrupting the timely delivery of meter reading data via route loops	Time-critical traffic data is not delivered on time	Time-sensitive control messages fail to be delivered
Sybil attacks (A_{14}) <i>Steal sensitive data</i>	Malicious devices claim several legitimate identities to cause jamming or DoS	Devices cause jamming or DoS in the smart transportation system	Devices cause jamming or DoS in the smart manufacturing system
Unauthorized access (A_{15}) <i>Disrupt device authentication</i>	Adversaries gain unauthorized access to smart meters	Adversaries gain unauthorized access to vehicles and RSUs	Adversaries gain unauthorized access to industrial sensors, actuators, and controllers

Internet of Things: Architecture, Key Applications, and Security Impacts, Table 3 Cyber-attacks in application layer and impacts

Attacks in application layer	Smart grid (Recall Fig. 2a)	Smart transportation (Recall Fig. 2b)	Smart manufacturing (Recall Fig. 2c)
Phishing attack (A_{16}) <i>Steal sensitive data</i>	Adversaries can obtain confidential data from smart meters	Adversaries can obtain sensitive data of vehicles, routes, and traffic in the smart transportation system	Confidential information in the smart manufacturing system is disclosed
Malicious virus/worm (A_{17}) <i>Cause damages</i>	Smart meters are infected by distributed self-propagating malicious software	Infected devices perform illegitimate function to harm the smart transportation system	Propagation and triggering endangers the smart manufacturing services, including smart plants, factories, etc.
Malicious scripts (A_{18}) <i>Cause damages</i>	Adversaries can run malicious scripts in smart meters to execute illegitimate functions	Adversaries run malicious scripts to disrupt smart transportation systems	Adversaries run malicious scripts to disrupt smart manufacturing applications

DoS attacks (e.g., distributed DoS), there exist massive numbers of attacking nodes. Note that how to quickly detect and effectively mitigate DDoS attacks remains an unresolved issue.

Cyber-Attacks in Application Layer

We use Table 3 to illustrate cyber-attacks on the smart grid, smart transportation, and smart manufacturing in the application layer, including phishing attacks (A_{16}), malicious viruses/worms (A_{17}), and malicious scripts (A_{18}), as well as the impacts of the cyber-attacks on the system.

Case Study

To better understand the cyber-attacks in IoT, we now present a case study on data integrity attacks on the smart grid system. Note that our designed methodology can be applied to other IoT-based systems, such as smart transportation system (Lin et al. 2018) and smart manufacturing system (Xu et al. 2018a; Wu et al. 2018).

For numerous reasons, including open network interfaces and the lack of tamper-resistant hardware in SCADA systems in the smart grid, a number of cyber-attacks could be leveraged by adversaries to disrupt the operation of power grid systems. For instance, an adversary could leverage malicious software to launch data integrity attacks, which inject false

data into the smart grid system and disrupt its operations, including the state estimation (Yang et al. 2014), energy pricing (Lin et al. 2016), and renewable and traditional energy resource integrity (Lin et al. 2012), among others. Notice that Stuxnet is one such malicious software that can be used to attack SCADA systems (Langner 2011).

To understand the impact of data integrity attacks on smart grid state estimation and design defensive schemes in response, Yang et al. (2014) addressed two issues: (i) how would an adversary choose the smallest number of smart meters to compromise in order to sufficiently manipulate a given number of states and (ii) how to detect malicious smart meters readings. To tackle the first issue, they formalized the least-effort attack model as an NP-hard problem and designed several heuristic algorithms to derive approximate optimal solutions. Regarding the second issue, they designed two detection schemes, one based on the temporal behavior of compromised meters and the other based on the spatial behavior of compromised meters. To defend against data integrity attacks on the state estimation in the smart grid, Yang et al. (2017) presented a protection-based defensive scheme that deploys highly secured phasor measurement units (PMUs). In this defense, a deployment algorithm was designed to not only derive the smallest number of PMUs that are sufficient to

defeat the attack but also to determine optimal locations for PMU deployment.

Future Directions

As future directions, we shall investigate risks of cyber-attacks, design effective defensive schemes, and leverage integrated evaluation platforms toward security-resilient smart grid, smart transportation, and smart manufacturing systems.

In particular, to investigate risks of cyber-attacks, we shall understand the system vulnerabilities from the perspectives of software, communication, and side-channel, among others (Lin et al. 2012; Yu 2012; Yu et al. 2015). Then, we shall investigate the impacts of system vulnerabilities in terms of key services, operation, and management in disparate IoT systems. Besides, we shall understand the optimal attack strategies (duration of an attack, spatial distribution, and scale, among others) for adversaries, which achieve their attack goals with minimum cost.

We shall study the design of defensive schemes from four stages, such as manufacturing stage, configuration stage, detection stage, and response stage (He et al. 2015; Lin et al. 2013; Yang et al. 2017, 2016). In manufacturing stage, the IoT devices, such as smart meters, RSUs, and controllers, and so on shall be designed and manufactured in a secure way (i.e., minimize vulnerabilities). In the configuration stage, the system configuration, including device deployment, software upgrade, and maintenance, shall be securely conducted. In the detection and response stages, the effective anomaly detection schemes and corresponding responsive plans shall be designed to detect cyber-attacks and mitigate caused damages.

Moreover, we shall leverage integrated evaluation platform to evaluate effectiveness of the defensive schemes. For smart grid, one co-simulation platform is the Fenix framework for Network Co-Simulation (FNCS), which

integrates GridLAB-D and NS-3. The FNCS can capture the interaction between power grid and communication network, as well as computational algorithms and cyber-attacks (Moulema et al. 2015). For the smart transportation, we can leverage integrated testbed, including OMNET++, SUMO, and Veins to describe the interactions between transportation system (SUMO) and communication network (OMNET++) via a Veins framework (Noori 2012). For the smart manufacture system, we can use the wireless cyber-physical simulator (WCPS) to describe the interactions between industrial control systems (Simulink) and communication network (TOSSIM) (Li et al. 2013; Ma et al. 2018; Ma and Lu 2018).

Final Remarks

IoT-based systems, such as the smart grid, smart transportation, and smart manufacturing engender tremendous benefits, including resource efficiency, convenience, productivity, and safety via massive collection, transmission, analysis of valuable sensor, and control information. Despite these benefits, security issues in IoT-based systems caused by vulnerability to cyber-attacks prevent their full realization and thus demand systematic investigation and consideration. In this entry, we first presented an IoT architecture and representative IoT-based systems and described insightful information flows. We then studied cyber-attacks on IoT-based systems and their impacts from the perspectives of the three-layer IoT architecture. We also presented a case study to demonstrate examples of cyber-attacks on the smart grid and discuss several future directions toward securing IoT-based systems.

Definitions

The Internet of Things is a large network of connected devices, which includes devices that are normally not capable of Internet connectivity or intelligent computation. The field of IoT security comprises all the different methods and countermeasures required to protect devices and networks within the Internet of Things with the goal of ensuring safe and reliable operations of the overarching systems and applications.

Historical Background

The Internet of Things has its roots in the earlier concepts of pervasive and ubiquitous computing. Everyday “dumb” devices could be equipped with embedded electronics to make them observe and interact with their surroundings. Following on from the progress of wireless sensor networks and automatic identification and data capture systems, the next step was to extend connectivity to these devices. This gave rise to the possibility of large networks of nontraditional computational devices. This leads to the generic architecture in Fig. 1, where we have a cloud of heterogeneous devices interacting with their surroundings and each other, which is connected to a back-end system, either directly via machine-to-machine communication or through a gateway. The back-end is responsible for processing potentially high-

volume data streams, data storage, analytics, and visualization. IoT architecture underpins many consumer and nonconsumer applications, from smart homes and healthcare to cyber-physical systems for industrial use in manufacturing and critical infrastructure monitoring.

As such, IoT devices are potentially an attractive target for attacks, and there has been several high-profile security incidents related to IoT devices. It is therefore critical that devices and networks are protected, but this is challenging. Securing devices is made difficult by a variety of device hardware and system restrictions including limited device energy, memory and processing resources, message size, and real-time operation. The scale in which IoT deployments are usually conducted requires that future solutions developed for the IoT should be highly scalable with an extended operational period. The IoT network should also be able to meet strict real-time deadlines, which means that communication latency and algorithm execution time should be predictable and minimal (Zhou et al. 2018).

Foundations

The subject of IoT security is very broad, covering security aspects of the devices, network communication, and the back-end platform. There are also many industry and academic opinions on this subject, with no definitive answer which aspects

IoT Security, Fig. 1 Generic system architecture

are most important. However, several high-level security themes have emerged that is found across different IoT-relevant security initiatives, such as the security frameworks by the Industrial IoT Consortium (ICC 2016) and OpenFog Consortium (OC 2016).

Tamper resistance: IoT devices are not deployed in physically secure locations and are open to tampering attacks. Attackers with access to devices can attempt several types of attacks to compromise device security, such as invasive, noninvasive, fault injection, and software attacks (Nisarga and Peeters 2016). Invasive attacks involve physical intrusion at device level, e.g., breaching the device enclosure to access device interfaces inside, or at integrated circuit (IC) level, e.g., depackaging an IC to access its internal structure. Noninvasive attacks observe external measurable behavior of the device, as security operations are carried out, and aim to extract sensitive data via side channels, e.g., electromagnetic analysis, power analysis, and timing analysis. Fault injection attacks occur when the attacker alters the environment or operating conditions of the device to cause a fault that compromises device security, e.g., over- or undervoltage attacks, over- or under-temperature attacks, and clock manipulation attacks. Software attacks can be launched by exploiting external debug interfaces, programming interfaces, and communication interfaces, which include the API security vulnerabilities, i.e., calling device commands/APIs, in ways that compromise security. To physically safeguard devices, the use of tamper-resistant hardware components and secure devices should be employed (ICC 2016). Mechanisms to detect tampering may be built into the device casing, such as enclosure monitoring sensors such as light, temperature, pressure, or vibration sensors (Nisarga and Peeters 2016), and attempts to access device hardware should be reported and devices in question isolated from the network. Tamper mesh can be employed for active tamper monitoring of the IC packaging but is typically only employed on ICs that are marketed as secure or security-hardened. Electromagnetic leakage shields could also be incorporated within the device enclosure

or IC packaging. The addition of amplitude or temporal noise in hardware or software could decrease the signal-to-noise ratios of side channels to counteract attacks.

Trusted execution: In addition to tamper resistance, the establishment of a root of trust is crucial for supporting mechanisms for device identification and integrity checking (ICC 2016). To create a secure root of trust for a networked device, there should ideally be a hardware root-of-trust mechanism such as a hardware-based trusted execution environment (TEE) implemented with a trusted platform module (TPM) (TCG 2008). TPMs can be used to provide storage, processing, and cryptographic functions such as encryption, decryption, key generation and storage, and data signing in a secured and isolated execution environment. This offers physical tamper resistance to protect sensitive data and cryptographic processing capture and physically and logically separates security and cryptographic functions from normal device operations. It can be used as the basis of secure device management and software provisioning, e.g., authenticity of the new applications verified, and the attestation of device integrity. Newer embedded processor architecture is starting to incorporate integrated, system-on-chip TPMs, while older devices could be hardened by adding an external TPM, such as a smartcard-based secure access module (SAM).

Attestation: The basis of attestation is that “the entity that is to be tested, called the prover, sends a status report of its current configuration to another party, called the verifier, to demonstrate that it is in a known and thus trustworthy state” (Asokan et al. 2015; Valente et al. 2014). This technique is utilized toward the assurance of device integrity. Remote attestation schemes assume that the prover is provided with a trusted mechanism such as a TPM, with integrity measurements being taken and securely stored during the secure boot process. When conducting the attestation, the verifier sends a request for the device configuration measurements, and the prover retrieves, hashes and signs the measurements through the use of a digital signature algorithm, and then sends this to the verifier. The

verifier then verifies the signature and compares the measurements against the expected measurements for the device configuration (Valente et al. 2014). Given the potentially large-scale and heterogeneous nature of IoT deployments, attestation is a challenging problem as it is difficult for the verifier to keep track of every possible device configuration connected at a particular time to the network. Devices might also not have a TPM and need to relay on software-based attestation, and ideally device and state integrity measurements should also be verifiable after boot to achieve run-time attestation (Asokan et al. 2015; Ibrahim et al. 2016).

Cryptographic mechanisms: Endpoint devices use cryptographic mechanisms to maintain confidentiality and integrity of execution state and data. Cryptographic mechanisms also secure the communications exchanged within the IoT network by providing authenticated, confidential channels between devices, gateways, and back-end systems. There are many well-known algorithms to choose from for building security mechanisms for symmetric encryption, e.g., AES; asymmetric encryption and digital signature, e.g., RSA; and data hashing, e.g., SHA-2. Elliptic-curve cryptography also allows for computationally efficient asymmetric signing, e.g., ECDSA, and key agreement, e.g., ECDH, with smaller key sizes compared to conventional asymmetric algorithms. Performing cryptographic operations on IoT endpoint devices has been considered a challenge owing to their resource-constrained nature. There is still merit in finding more efficient cryptographic algorithm implementations for IoT devices as in some applications memory and operational latency is important. However, with recent advances in processing and storage technologies, new generation of IoT processors is feasibly capable of running standard symmetric and asymmetric cryptographic without negatively impacting the device ability to support other network operations (Ledwaba et al. 2018). This allows the possibility of using and optimizing standard, strong cryptographic functions rather than there

being a need to design new cryptographic algorithms.

System monitoring and intrusion detection: Within the IoT application space, sensor devices capture and transmit data pertaining to their deployment environment up toward the main network processing environment for analysis and actuation in data streams (Bertino et al. 2016). Owing to the nature of IoT networks, infiltration, data capture, and modification may occur without detection as streams are transferred from the network edge up to the cloud. To assist in providing the continued integrity in the network operations, intrusion detection and prevention techniques are often utilized. In comparing historic analytics of device data and network traffic with real-time data, these intrusion detection techniques are then capable of signaling to the wider network when unauthorized device or network behavior occurs (Midi et al. 2017). This aids in detecting security attacks on the system early in the process, making a successful defense more likely. The main problem is that while data analytic methods are moving forward, the provision of data verification, confidentiality, and integrity of the data streams generated in an IoT network remains an open research question, while device monitoring solutions for the IoT such as intrusion detection are still largely academic.

Key Applications

The Internet-of-Things paradigm is used in a number of applications ranging from consumer electronics to industrial and cyber-physical systems. IoT security plays a role in protecting such systems and ensuring their safe and reliable operation.

Definitions

Adaptive video streaming is a popular video delivery technique which could adjust the quality level of a video stream to adapt the dynamic network conditions and support heterogeneous devices (e.g., TV, PC, tablet, and smartphones). By utilizing video transcoding, the original content could be transcoded to a preconfigured format (e.g., codec, resolution, and bitrate) for meeting the requirements of users. In general, it is necessary to manage resources to cache video contents and transcode them to overcome the diversity issues presented by the multiple formats of video streams. However, the on-demand provisioning, scalable resource management, and routing optimization pose significant challenges to the existing network operators.

Wireless edge caching, as an extension of in-network caching, can efficiently reduce the duplicate content transmission and improve the quality of services (QoS) of users. By caching a number of popular contents proactively at the network edge, the desired contents can be delivered with the short-range communications between the small base stations (SBSs) and users directly. This is able to significantly improve the network performance, e.g., transmission delay and energy efficiency. However, due to the limited storage size of network edge, it is important to decide

what content to cache and how to select route-path taking into account content popularity and network conditions.

Mobile edge computing (MEC), which utilizes the powerful computing capabilities at the edge of the networks, has been recognized as a promising solution to process and transcode video streams for the users. The basic idea behind MEC is that by transcoding video into different formats in close-proximity to the users, huge backhaul burden is released and user's experience is improved. When the SBSs do not have enough computing resources to process their video contents, they have to perform routing selection and forward their users' requests to the remote cloud server at the expense of consuming more network resources and higher communications latency. Thus, the resource management and routing optimization issues play an important role in improving resource utilization and QoS of users.

Historical Background

Traditionally, video streaming solutions utilize either a UDP-based (RTP/RTSP and IP-layer multicast) or TCP-based (RTMP) approach to optimize video delivery efficiency. Currently, the HTTP-based solution is widely used due to the advantages of its extensive infrastructure, servers, and caching. However, in varying wireless networks, it is critical to adapt to the network conditions for providing better services to users. To overcome such challenges, in adaptive bitrate streaming (HLS (HTTP Live Streaming (HLS) 2014), DASH (Stockhammer 2011)), the video file is partitioned into multiple segments each of which has a duration of a few seconds. Then the service server maintains different bitrates of the same video segments and delivers them to users with distinct preferences. Recently, edge caching and computing techniques attract a lot of researches for improving the performance and efficiency of video distribution, by carefully allocating network resources (e.g., caching, transcoding, and routing).

Wireless edge caching refers to that SBSs cache the video segments and delivers them to the users directly, reducing response delay and

network traffic. The benefits of wireless edge caching have been demonstrated in various types of wireless networks (Tan et al. 2018; Wang et al. 2017). Due to the limited caching resources and large-scale contents within networks, it is beneficial to apply popularity prediction (Cho et al. 2012) and proactive caching (Zhang et al. 2017) for deciding what content to cache. On the other hand, routing policies, deciding where to obtain the contents, are also crucial for overall caching performance. Deh et al. (Liu et al. 2017) propose a unified optimization for the joint caching and multi-relay problem to improve the caching and bandwidth utilization. He et al. (He and Song 2016) propose a hop-by-hop routing protocol, which implements the optimization solutions by generating a set of flow-splitting and routing decisions to reduce the overall networking cost.

MEC has recently received significant research attention for handling video services. A MEC-based architecture, where each MEC server could modify the bitrate version of the video on the fly according to current network conditions, is proposed in (Liang et al. 2017) to improve the performance of adaptive video streaming. Considering the varying wireless channel conditions, a video bitrate adaptation algorithm is proposed in Pedersen and Dey (2016) to joint optimize radio access network caching and computing. To improve resources utilization, the authors in Liu et al. (2018) investigate the dynamic resource allocation for transcoding and delivering adaptive video streaming services. By combining caching and routing issues, the authors in Jin et al. (2015) investigate the NFV-based resource allocation and SDN-based routing for cost-efficient video distribution over future networks.

Foundations

In wireless networks, a large number of end devices, such as smart devices, wearable devices, tablet, connect to the SBSs through reliable and efficient access networks. These end devices may generate amounts of video service and application requests that are sent to the network edge. Then, the SBSs with the capabilities of

caching, computing, and network connectivity will process and transmit video contents to different users. Because of the tremendous amount of accessible contents over the Internet and limited storage at the SBSs, those caching contents cannot include all of them within the networks. Since each SBS caches partial content segments, there would be three possible cases to provide content to the user, including exact cache case, transcoding cache case, and cache miss case.

The content response delay, which can be directly translated into user's QoS, plays an important role in improving the user's experience. In the case of exact cache scenario, since the SBS transmits the content segments directly to the user, there is only access delay, which can be derived by following the rule that the ratio of the total bitrate of the required segments and the transmission rate. In the case of transcoding cache, the SBS has to transcode the higher bitrate version into the required bitrate version, which may incur transcoding delay and computing resource cost. Then, the delay of the transcoding cache case can be derived as the sum of the access delay and the transcoding delay. Lastly, in the case of cache miss, the SBS has to forward the request to the remote cloud server and obtains the content segment via the backhaul links. It will incur great delay and backhaul cost. The total cache miss delay includes the access delay and the backhaul delay that are related to the available backhaul rate.

To access a piece of content, a user must decide whether to route its request to an SBS or to the remote cloud server. Resource management policy (e.g., caching and computing resources) should also be well designed to minimize the content response delay. To address these issues, the optimization problem is divided into two stages: routing selection and resource allocation. Firstly, when the user broadcasts the content request to the neighboring SBSs, each SBS that receives the request will estimate the delay by providing all the required contents to the user with a given resource allocation policy. Under the resource constraints, each user would select a set of SBSs following the rule that the total delay is minimized. Then, given the routing selection, caching and computing resources allocation

problem could be formulated as a convex optimization problem and is easy to solve.

Key Applications

The joint caching, computing, and routing strategies play an important role in adaptive video streaming services. It can be further applied to various types of systems, for instance, intelligent medical system, monitoring system, and vehicular networks.

Definition

Opportunistic routing and network coding are promising network paradigms. Both of them benefit from the broadcast nature of wireless media and will significantly improve network performance. Network coding applies algebraic algorithms to code data packets; each coded packet randomly combines partial information of different data packets, which extends the distribution of data packets in the network. Since each coded packet is equally beneficial and inherently different and each coded packet contains part of information from different original packets, no coded packet is special or indispensable. Thus, even though some coded packets are lost, the sender can keep forwarding coded packets without learning which packets are lost. Opportunistic routing considers multiple downstream nodes are potential next-hop forwarders, which can effectively reduce the possibilities of unnecessarily reconstruction path or retransmission due to link breakage on a preselected path.

Historical Background

Network coding represents an innovative idea introduced by Ahlswede et al. in 2000 (Ahlswede et al. 2000). It has emerged as an important potential approach to the operation of communication networks, especially wireless networks. The major benefit of network coding comes from its ability to code data, across time and across flows. It makes data transmission over lossy wireless networks robust and effective. There has been a rapid growth in the theory and potential applications of network coding. These research can be summarized in two types of network coding: inter-flow network coding that mixes packets from different sources and intra-flow network coding that is about fusing packets from the same source.

Opportunistic routing allows multiple nodes to overhear packet transmissions and be involved in further forwarding packets. With intra-flow network coding, packets from the same flow are coded; each coded packet is equally bene-

ficial and inherently different. Since no special coded packet is dispensable, the deficit information from lost packets can be easily filled by following coded packets. The combination of these two ideas in a natural fashion to provide opportunistic routing without a coordination and exploit opportunity gains inherent in wireless media.

Foundations

In general, the linear network coding is different from the *xor* operation by a linear combination of the data, which interprets data over some finite fields, e.g., $GF(2^s)$. It allows a much larger degree of flexibility to combine packets. With the linear network coding, coded packets are linear combinations of original packets. The coding process of addition and multiplication is performed over the finite field. The finite field or Galois field is a field that contains a finite number of elements. A finite field is a set on which the operation of multiplication, addition, subtraction, and division are defined and satisfy certain basic rules (Lidl and Niederreiter 1997). Addition is the standard bitwise *xor*. Division is computed by the Euclidian algorithm (Fragouli et al. 2006a). Both multiplication and division can be implemented efficiently with s shifts and additions (Wagner 2003).

Intra-flow network coding will code packets from the same flow. One simple example of the intra-flow network coding can consider a linear topology with three nodes. Source node S will directly send n packets to destination D . The packet delivery probability is 50% in both directions. Without network coding, the source node requires the ack to learn whether a packet is received by the destination. Thus, the expected number of transmissions will be $2n + 2n$ ($2n$ for data packets, $2n$ for acks). Network coding allows nodes to make the random linear combination of data packets. Once the destination receives n independent coded packets, it can decode n original packets. Then the destination sends one ack for all n packets. The expected number of transmissions will be $2n + 2$.

The detail discussion about intra-flow network coding as follows.

Encoding at Source

Assume that the number of original packets is defined as $O^1, O^2, \dots, O^n$ and each packet consists of L bits. Original packets will be divided into several symbols with the same length. When original packets to be combined do not have the same size or the length of the original packets cannot be equally divided into symbols with the same length, the shorter packets are padded with trailing 0 s. The s consecutive bits of a packets are defined as a symbol over the finite field $GF(2^s)$; therefore, each packet consists of $K = L/s$ symbols. In linear network coding, each packet through the network is associated with a sequence of coefficients $g^1, g^2, \dots, g^n$ in $GF(2^s)$. The coded packet is equal to $C = \sum_{i=1}^n g^i O^i$. The summation will occur at every symbol position k ; for example, the coded symbol $C_k = \sum_{i=1}^n g^i S_k^i$, where S_k and C_k are the k th position of original symbol and coded symbol, respectively. We show one example of the encoding process in Fig. 1.

After packets are coded together, each coded packet contains both a set of coefficients $G = \{g^1, g^2, \dots, g^n\}$, called encoding vector and coded data $C = \sum_{i=1}^n g^i O^i$, called information vector (Fragouli et al. 2006a). The encoding vector is used by receivers to decode original packets. For example, the encoding vector $G = \{0, \dots, 1, \dots, 0\}$, where the 1 is at the i th position. It means that the information vector is equal to the original packet O^i .

In the linear network coding, the selection of the coefficients for each linear combination is an important issue for practical considerations. A simple algorithm is that each node in the network selects random coefficients over the field $GF(2^s)$ in a completely independent and decentralized manner (Ho et al. 2003). With the random network coding, there is a still certain probability of selecting linearly dependent combinations. However, this probability can be reduced by choosing large field size 2^s (Fragouli et al. 2006a). Simulation results show that even for small field

Joint Network Coding and Opportunistic Forwarding, Fig. 1 An example of encoding in network coding

Joint Network Coding and Opportunistic Forwarding, Fig. 2 An example of recoded in network coding

sizes (e.g., $s = 8$), this probability is still negligible (Wu et al. 2004).

Recoding at Intermediate Nodes

The encoding process in linear network coding can be performed recursively. Therefore, the intermediate node can recode the coded packet. Consider that a node receives a set of coded packets $(G^1, C^1), \dots, (G^m, C^m)$, shown in Fig. 2, where G^m is the encoding vector and C^m is the information vector. This intermediate node will generate a new set of coefficients $H = \{h^1, h^2, \dots, h^m\}$ and compute the linear combination $RC = \sum_{i=1}^m h^i C^i$. The new corresponding encoding vector G' is not simply equal to H , since the coefficients need to be generated with respect to the original packet $O^1, O^2, \dots, O^n$, the

new encoding vector will be $G' = \sum_{i=1}^m h^i G^i$ (Fragouli et al. 2006a). This operation can be repeated at intermediate nodes several times in the network.

Decoding at Destination

Assume that the destination node receives a set of coded packets $(G^1, C^1), \dots, (G^m, C^m)$. In order to decode the original packets, the destination node needs to solve the linear system $C^i = \sum_{j=1}^n G^i O^j$, where $G^i = g_i^1 \dots g_i^n$

$$\begin{pmatrix} C^1 \\ \vdots \\ C^m \end{pmatrix} = \begin{pmatrix} g_1^1 \dots g_1^n \\ \vdots \\ g_m^1 \dots g_m^n \end{pmatrix} \times \begin{pmatrix} O^1 \\ \vdots \\ O^n \end{pmatrix} \quad (1)$$

The unknowns are O^i , and this system is a linear system with m equations and n unknowns. If the number of received packets in the destination node is equal to or larger than the number of unknowns, the destination has a chance of decoding all original packets. Here, the decoding condition that the number of received packets is larger than the number of unknowns ($m < n$) is not sufficient, because some of the coded packets may be linearly dependent.

The destination node will solve a set of linear equations. This process can be done as follows. It stores the encoded vectors from the received coded packets in a decoding matrix (Fragouli et al. 2006a). When an encoded packet is received, the encoded vector of this packet will be inserted as the last row of the decoding matrix. When this matrix will be transformed based on the current encoded vectors, the matrix will be transformed to a reduced row echelon form using Gaussian elimination, where the leading term of each row is 1 and the position of the leading terms moves to the right. A received packet is called innovative if its encoded vector increases the rank of the matrix. As soon as the matrix contains n rows, where n is the number of original packets, the destination node can decode all original packets. The size of the decoding matrix has great impact on the decoding delay at the destination (Chou et al. 2003). For practical considerations, this size of decoding matrix should be limited. Therefore, packets are usually grouped into batches or generations, and only packets of the same generation can be combined. The size of batches also has significant impact on the performance of network coding (Fragouli et al. 2006b).

Advantage of Jointed Protocols

Opportunistic routing improves network performance by exploiting the broadcast nature of wireless media. The main concern of opportunistic routing is how to utilize all possible paths to deliver packets with available cost. A reliable coordination mechanism for opportunistic routing is always challenge work and hard to carry out accurately. The protocols of using network cod-

ing can eliminate the unnecessary acknowledgment in opportunistic routing. The architecture design of network layers can be independent since no feedback information is required from MAC layer to network layer. On the other hand, the major challenge of network coding is how to find an efficient way to explore the coding opportunistic in the network for which opportunistic routing seems a promising approach. Therefore, the advantage of joint protocols is to use the strengths of one to overcome the weakness of the other (Ho et al. 2003).

Key Applications

Network coding applications deal with unreliable transmissions in wireless and content distribution networks. Opportunistic routing can further explore the coding opportunity. They are expected to be critical technologies for networks of the future. Multiple unicasts, security, networks with unreliable links, and quantum networks can be discussed with network coding.

Definition

Long-Term Evolution (LTE) is a standard developed by the 3GPP (3rd Generation Partnership Project) for high-speed mobile communication based on the GSM/EDGE and UMTS/HSPA technologies, commonly known as 3.9G (beyond 3G but pre-4G), that is, the version from HSPA transition to 4G. LTE is specified in the 3GPP Release 8 and 9 document series, and it can provide 300 Mbit/s peak rates for downlink, 75 Mbit/s for uplink, and less than 5 ms for latency. 4G

is a continual improvement standard to the LTE radio technology and architecture, which is also called International Mobile Telecommunications Advanced (IMT-Advanced) as defined by the International Telecommunications Union-Radio communications sector (ITU-R) (https://en.wikipedia.org/wiki/LTE_Advanced). 4G is specified in the 3GPP Release 10 and known as LTE-Advanced, and it can provide 100 Mbit/s peak rates for high mobility and approximately 1 Gbit/s for low mobility (<https://en.wikipedia.org/wiki/4G>). On the whole, LTE is pre-4G technology that brings the 3G networks to a new 4G performance era radically; LTE-Advanced is real 4G technology that reaches the target set for IMT-advanced (ITU-R 2008).

To enable better performance than 3G, 4G/LTE network has applied some efficient key technologies (3GPP TR 36.814 2010): (1) Orthogonal Frequency Division Multiplexing (OFDM); (2) Multiple-input Multiple-output (MIMO); (3) Mobile IP; (4) Software Defined Radio (SDR); (5) Link adaptation, and (6) Small cell.

Historical Background

Currently, 4G/LTE is good enough for most mobile users and will be there for some time (<https://en.wikipedia.org/wiki/4G>). To understand 4G/LTE, it is essential to look back to the ongoing process of wireless cellular technologies since the incipency of 1G almost

forty years ago. 1G was introduced in the early 1980s, which is an analog communication system that established seamless mobile connectivity introducing mobile voice services at speeds of up to 2.4 kbit/s. 2G digital wireless technologies can increase voice capacity, and the most popular 2G technology was Global Systems for Mobile Communications (GSM) with SMS messaging. 3G, which is required to meet IMT-2000 technical standards, improved the data speeds up to 2 Mbit/s for indoor or stationary users, 384 kbit/s for pedestrians, and 144 kbit/s for moving vehicles. In more recent years, 3G has made some advancements, for example, HSPA, which is often called 3.5G or Turbo 3G, can offer theoretical speeds up to 7.2 Mbit/s. Better than 3G, 4G/LTE has many specific characteristics (Anitha and Joshphin 2015).

- (a) **Faster Speed:** As we mentioned above, the 4G/LTE system should provide more than 100 Mbit/s peak rates at rest and an average of 20 Mbit/s when in motion. It is clear that the speed is much higher than 3G.
- (b) **Seamless handover:** 4G/LTE networks support global roaming across multiple wireless and mobile networks. This provides greater flexibility for vendor selection.
- (c) **Better network capacity:** The capacity at least 10 times than that of 3G, which means that the download time of a 10 Mbyte file is quickened to one second on 4G/LTE networks comparing with 200 s on 3G networks. This enables better user experience.

Foundations

Key technologies in 4G/LTE networks are mainly described below:

Orthogonal Frequency Division Multiplexing (OFDM)

In OFDM, the signal is divided into orthogonal subcarriers, the signal is “narrowband” on each subcarrier and therefore is not affected by multipath, as long as a guard interval is inserted between each OFDM symbol. OFDM can pro-

vide (1) significant advantages for physical layer performance and (2) a framework for improving layer 2 performance by providing additional degrees of freedom (Al-Kebsi et al. 2009). Using OFDM, the time domain, air domain, frequency domain, or even code domain can be utilized to optimize the use of wireless channels. In OFDM, the transmission in a multipath environment is very robust and the receiver complexity is lowered.

Orthogonal Frequency Division Multiple Access (OFDMA), a multiple access technique, is the evolution of OFDM technology. In this case, each OFDM symbol may use a different set of subcarriers (subchannels) to send information to multiple users or to send information from multiple users (Holma and Antti 2009). This can provide additional flexibility for resource allocation (increase capacity) and enable cross-layer optimization of spectrum usage.

The major disadvantage of an OFDM system is High Peak to Average Power Ratio (PAPR) due to the summation of a large number of subcarriers coherently. 4G/LTE system have applied several techniques to reduce the PAPR, including clipping, peak windowing, and peak cancellation.

Multiple-input Multiple-output (MIMO)

MIMO referred to the use of multiple antennas at the transmitter and the receiver to achieve the goal of 4G/LTE networks (Di Renzo et al. 2014). MIMO can improve the spectrum efficiency of 4G/LTE system directly or indirectly. MIMO technology can be classified into four main categories: (1) spatial diversity, (2) beamforming, (3) space division multiplexing, and (4) space division multiple access. Spatial diversity and beamforming can improve the link quality, enhance coverage, and indirectly improve the spectrum efficiency; space division multiplexing and space division multiple access can improve the user capacity and directly improve the spectrum efficiency. In spatial diversity, a single stream is transmitted using space-time coding, which exploits the independent fading in the multiple antenna links to enhance signal diversity. Beamforming is a signal precoding technology based on the antenna array, and it can produce

directivity beam by adjusting the weighting coefficient of each antenna array, thus to obtain obvious array gain. In space division multiplexing, a high-rate signal is split into multiple lower-rate streams and each stream is transmitted from a different transmit antenna in the same frequency channel for link capacity enhancement.

Mobile IP

Mobile IP (or MIP) is an Internet Engineering Task Force (IETF) standard communications protocol that is designed to allow mobile device users to move from one network to another while maintaining a permanent IP address (https://en.wikipedia.org/wiki/Mobile_IP). Data may be lost during the time when a mobile node moves between domains of a network and hence effects the Quality of Service (QoS) of the mobile node. In order to solve this problem, the mobility management scheme is used to reduce the movement detection latency and maintain the IP connectivity. On the other hand, Session Initiation Protocol (SIP) is used for signaling and controlling multimedia communication sessions in applications of Internet telephony for voice and video calls to support fast handoff (https://en.wikipedia.org/wiki/Session_Initiation_Protocol).

Software Defined Radio (SDR)

The final form of a 4G/LTE device constitutes various standards, such like 2G, 3G, 4G. SDR is a single radio that can be used for many modes by simply reconfiguring the radio with different software (Tripathi et al. 2015). Such a design produces a radio which can receive and transmit widely different radio protocols based solely on the software used (https://en.wikipedia.org/wiki/Software-defined_radio). This flexible architecture can improve performance in terms of power consumption and reduced interference. SDR becomes an enabler for the aggregation of multistandard pico-/microcells in 4G/LTE networks. This is a powerful aid to provide multistandard, multiband equipment through simultaneous multichannel processing.

Link Adaptation

The basic idea of link adaptation is to adjust transmission parameters and schemes to take advantage of variations in channel conditions (Zheng et al. 2005). The most efficient link adaptation techniques are adaptive modulation and coding (AMC) and hybrid-automatic request repeat (H-ARQ). AMC changes the modulation and coding format according to variations in channel conditions, through explicit signal-to-noise ratio (SNR) measurements. H-ARQ is a combination of high-rate forward error-correcting coding and ARQ error-control, and it is an implicit link adaptation technique (https://en.wikipedia.org/wiki/Hybrid_automatic_repeat_request). It is the best use of combining AMC with H-ARQ in 4G/LTE networks, while AMC provides gross data rate selection as well as that H-ARQ adjusts the data rate based on channel conditions. In 4G/LTE system with OFDM and MIMO technologies, link adaptation can improve rate of transmission, and/or bit error rates, and exhibit great performance enhancements compared to systems that do not exploit channel knowledge at the transmitter (https://en.wikipedia.org/wiki/Link_adaptation).

Small Cell

In 4G/LTE networks, the principle of heterogeneous network is introduced where the mobile network is constructed with layers of small and large cells. Small cells are low-powered cellular radio access points that operate in licensed or unlicensed spectrum. Compared to a mobile macrocell, they have a shorter range and typically handle fewer concurrent calls/sessions. In 4G/LTE system, larger numbers of small cells are deployed to increase cellular network capacity, quality, and resilience. Small cells may encompass femtocells, picocells, microcells, and distributed radio technology using centralized baseband units and remote radio heads. The cost advantages of small cells compared with macrocells make it economically feasible to provide coverage of much smaller communities. Small cells also help service providers discover new revenue opportunities through their location

and presence information (https://en.wikipedia.org/wiki/Small_cell).

Key Applications

Compared with previous mobile network technologies, 4G/LTE offers much higher bandwidth, lower latency, and improved spectrum efficiency (Akayama et al. 2012). In practice, this activates more applications to be used on mobile devices, improves the performance of many existing applications, and makes feasible new applications depending on reliable high-speed such as real-time sharing of large files and streaming media. The improved convenience, user experience, and practicality of 4G/LTE also hasten uptake of those existing applications that already work on mobile devices.

Definitions

A *unimodular matrix* $\mathbf{U}$ is a square integer matrix whose determinant is 1 or -1 .

A *lattice* is a set of all integer linear combinations of a group of linearly independent vectors. More formally, for a given full column rank matrix $\mathbf{A} \in \mathbf{R}^{m \times n}$, the lattice $\mathcal{L}(\mathbf{A})$ generated by $\mathbf{A}$ is defined as $\mathcal{L}(\mathbf{A}) = \{\mathbf{A}\mathbf{x} | \mathbf{x} \in \mathbf{Z}^n\}$. For example, if $\mathbf{A}$ is an $n \times n$ identity matrix, then $\mathcal{L}(\mathbf{A})$ is $\mathbf{Z}^n$. The matrix $\mathbf{A}$ is referred to as a *basis matrix* of $\mathcal{L}(\mathbf{A})$, and n is known as the *dimension* or *rank* of $\mathcal{L}(\mathbf{A})$.

Lattice reduction: for any $n \times n$ unimodular matrix $\mathbf{U}$, $\mathbf{AU}$ is also a basis matrix of $\mathcal{L}(\mathbf{A})$. Therefore, $\mathcal{L}(\mathbf{A})$ has infinitely many basis matrices if $n \geq 2$. Lattice reduction refers to the process of selecting an $n \times n$ unimodular matrix $\mathbf{U}$

such that $\mathbf{AU}$ has some “nice properties”. Usually, “nice properties” of $\mathbf{AU}$ refers to its column vectors are short and close to be orthogonal.

Wireless sensor network is a large number of geographically separately distributed sensors aiming to monitor the physical environment with a central unit that collects all the data from sensors. Wireless sensor networks are widely used to simultaneously monitor many environmental conditions, such as incident, forest fire detection, air pollution monitoring, machine health monitoring, wine production temperature, sound, and so on (Deng et al. 2017; Chen et al. 2017).

Historical Background

Lattice reduction has been studied for more than two centuries. More specifically, the idea of reduction dated back to C. F. Gauss who proposed a reduction, which is called as Gauss reduction later, in 1801 (Gauss 1801). Gauss reduction, which was defined for lattice with dimension 2, was generated to arbitrary dimension by Hermite in (Hermite 1850), and this reduction is referred to as Hermite reduction. A number of other reduction techniques were developed later; this includes Hermite-Korkine-Zolotareff (HKZ) reduction (Korkine and Zolotareff 1873), Minkowski reduction (Minkowski 1896), Brun’s reduction (Brun 1919, 1920), Lenstra-Lenstra-Lovász (LLL) reduction (Lenstra et al. 1982), and Seysen’ reduction (Seysen 1993). Among these reduction strategies, Minkowski reduction, HKZ reduction, and LLL reduction are the most popular three lattice reduction techniques, so their criteria and progresses are introduced as follows.

Minkowski reduction (Nguyen and Stehlé 2009): a basis matrix $\mathbf{A}$ is called Minkowski-reduced if for any $1 \leq i \leq n$ and $\mathbf{x} \in \mathbf{Z}^n$ with the greatest common divisor of the entries of $\mathbf{x}$ being 1, we have $\|\mathbf{Ax}\|_2 \geq \|\mathbf{A_i}\|_2$.

The first Minkowski reduction algorithm was proposed by Lagrange, but it only works for $n = 2$ (Lagrange 1773). The first Minkowski reduction algorithm for $n = 3$ and $n = 4$ were, respectively, developed in (Semaev 2001) and

(Nguyen and Stehlé 2009). Minkowski reduction algorithms for arbitrary n were independently developed in (Helfrich 1985) and (Afflerbach and Grothe 1985).

The criteria of HKZ reduction and LLL reduction techniques can be characterized by the R-factor of the QR factorization of $\mathbf{A}$. Let $\mathbf{A}$ have the QR factorization $\mathbf{A} = \mathbf{QR}$, where $\mathbf{Q} \in \mathbf{R}^{m \times n}$ is a matrix with orthonormal columns and $\mathbf{R} \in \mathbf{R}^{n \times n}$ is an upper triangular matrix. Then HKZ reduction is formally defined as follows:

HKZ reduction: a basis matrix $\mathbf{A}$ is called HKZ reduced if the R-factor $\mathbf{R}$ of the QR factorization of $\mathbf{A}$ satisfies $|r_{ij}| \leq \frac{1}{2} |r_{ii}|$ for $1 \leq i < j \leq n$ and $|r_{ii}|$ is the length of a shortest vector of lattice $\mathcal{L}(\mathbf{R}_{i:n,i:n})$, where $\mathbf{R}_{i:n,i:n}$ denotes the submatrix of $\mathbf{R}$ with columns and rows from i to n .

HKZ reduction is often simply called as KZ reduction (see, e.g., Agrell et al. 2002), and it was also called as Hermite reduction in (Helfrich 1985). The first HKZ reduction algorithm was developed by Kannan in 1983 (Kannan 1983). Since then, a number of improved HKZ reduction algorithms have been developed, see, e.g., (Agrell et al. 2002) and (Wen and Chang 2015).

LLL reduction: a basis matrix $\mathbf{A}$ is called LLL reduced (Lenstra et al. 1982) if the R-factor $\mathbf{R}$ of the QR factorization of $\mathbf{A}$ satisfies $|r_{ij}| \leq \frac{1}{2} |r_{ii}|$ for $1 \leq i < j \leq n$ and $\delta r_{ii}^2 \leq r_{i,i+1}^2 + r_{i+1,i+1}^2$, where $\delta \in (1/4, 1]$. Note that these two conditions are, respectively, referred to as size reduction and Lovász conditions.

The LLL reduction algorithm can be found in (Lenstra et al. 1982), and it has many improvements and variants, see, e.g., (Wen and Chang 2017). The complexity of reducing an n -dimensional integer matrix is a polynomial of n (Lenstra et al. 1982). However, HKZ reduction algorithms are supposed to be NP-hard since they need to solve shortest vector problems which are suspected as NP-hard problems.

If a basis matrix $\mathbf{A}$ is HKZ reduced, then it is also LLL reduced, but the inverse usually does not hold. HKZ reduction is frequently better than the LLL reduction in shortening the lengths of basis vectors and reducing the orthogonality of basis matrices.

Key Applications

Lattice reduction has important applications in many areas, such as number theory, cryptography, Global Positioning System (GPS), and wireless sensor network. For more details, see, e.g., (Nguyen and Vallée 2010) and (Wübben et al. 2011). In these applications, lattice reduction is often used to optimally or suboptimally solving a closest vector problem (CVP) or a shortest vector problem (SVP). For a given n -dimensional vector $\mathbf{y}$ and a given full column rank matrix $\mathbf{A}$, the CVP is the problem of finding the vector in lattice $\mathcal{L}(\mathbf{A})$ that is closest to $\mathbf{y}$. Thus, mathematically, it can be expressed as $\min_{\mathbf{x} \in \mathbb{Z}^n} \|\mathbf{y} - \mathbf{A}\mathbf{x}\|_2$. For a given full column rank matrix $\mathbf{A}$, the SVP is the problem of finding the shortest nonzero vector in lattice $\mathcal{L}(\mathbf{A})$. Thus, mathematically it can be expressed as $\min_{\mathbf{x} \in \mathbb{Z}^n \setminus \mathbf{0}} \|\mathbf{A}\mathbf{x}\|_2$.

Some applications of lattice reduction are briefly introduced in the following.

Applications of lattice reduction in number theory Lattice reduction has many applications in number theory. One of the applications, which is also mentioned in (Lenstra et al. 1982), is to simultaneous diophantine approximation. Specifically, for any given integer n , real numbers $y_1, y_2, \dots, y_n$ and ε which satisfies $0 < \varepsilon < 1$, the LLL reduction can find integers $x_1, x_2, \dots, x_n, \alpha$ such that $|x_i - \alpha y_i| \leq \varepsilon$ for $1 \leq i \leq n$ and $1 \leq \alpha \leq 2^{n(n+1)/4} \varepsilon^{-n}$. The integers $x_1, x_2, \dots, x_n, \alpha$ can be obtained through using the LLL reduction to reduce the basis matrix $\begin{pmatrix} \mathbf{I} & \mathbf{y} \\ \mathbf{0}^T & 2^{-n(n+1)/4} \varepsilon^{-(n+1)} \end{pmatrix}$, where $\mathbf{I}$ is the $n \times n$ identity matrix; $\mathbf{y}$ is an n -dimensional column vector whose entries are $y_1, y_2, \dots, y_n$; and $\mathbf{0}$ is an n -dimensional zero column vector. For more details, see (Lenstra et al. 1982). In addition to the above application, LLL reduction has many other applications in number theory; for more details, see, e.g., (Nguyen and Vallée 2010, Chapter 7).

Applications of lattice reduction in cryptography Lattice reduction, especially the LLL reduc-

tion, has many applications in cryptography, such as solving the problems of RSA, factoring integers, finding discrete logarithms, and solving the subset sum problem. For more details, see, e.g., (Nguyen and Vallée 2010, Chapters 10 and 11). Usually in these applications, an SVP or a CVP needs to be solved. LLL and/or HKZ reduction can be used to improve the efficiency of exactly solving SVP and CVP. It can also be used to suboptimally solve the SVP. Specifically, the first vector of the LLL-reduced matrix of $\mathbf{A}$ can be used as a suboptimal solution of the SVP. After performing the LLL reduction to $\mathbf{A}$, the Babai's nearest plane algorithm can be used to find a good suboptimal solution of the CVP.

Applications of lattice reduction in GPS In GPS, one needs to detect an n -dimensional integer vector $\mathbf{z}$ and a three-dimensional real vector $\mathbf{x}$ from the linear model $\mathbf{y} = \mathbf{A}\mathbf{z} + \mathbf{B}\mathbf{x} + \mathbf{v}$, where $\mathbf{y} \in \mathbb{R}^m$ is the difference of the observed vector and computed double-difference carrier-phase measurements; $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{m \times 3}$ are the design matrices for ambiguity terms and baseline components, respectively; $\mathbf{z}$ and $\mathbf{x}$ are, respectively, the vectors of unknown double-difference ambiguities and unknown baseline components; and $\mathbf{v}$ is the vector of measurement noise. For more details, see (Teunissen et al. 1997) and (Hassibi and Boyd 1998). To get a maximal likelihood estimator of $\mathbf{z}$, a CVP needs to be solved. Thus the LLL reduction can be used to improve the efficiency of getting an optimal solution of the CVP and improve the effectiveness of the Babai's nearest plane algorithm, which is an effective suboptimal algorithm for the CVP.

Applications of lattice reduction in wireless sensor network Suppose that a wireless sensor network is composed of a collection of low-end data collection nodes which are connected to high-end data collection nodes through a wireless link, and there are m transmitting data collection nodes and n receiver antennas at the data gathering node. Then the received discrete time signal over a narrow-band, flat fading wireless link can be expressed as $\mathbf{y} = \mathbf{A}\mathbf{x} + \mathbf{v}$, where $\mathbf{y}$, $\mathbf{x}$, and $\mathbf{v}$ are, respectively, m -dimensional received signal,

n -dimensional transmitted signal whose entries are some discrete numbers, and n -dimensional noise signal, and $\mathbf{A} \in \mathbf{R}^{m \times n}$ is the matrix of complex fading coefficients. For more details, see (Jayaweera 2007). To get a maximal likelihood estimator of $\mathbf{x}$, a CVP needs to be solved. Thus, lattice reduction can be used to improve the efficiency or effectiveness of detecting $\mathbf{x}$.

In addition to the above applications, lattice reduction has many other applications, which includes integer optimization (see, e.g., Nguyen and Vallée 2010, Chapter 9), transportation, and so on.

Learning-Based Secure Mobile Offloading

Liang Xiao

Department of Communication Engineering,
Xiamen University, Xiamen, China

Definition

Learning-based secure offloading strategy applies the reinforcement learning algorithms to derive the optimal data offloading and defense policy for the mobile devices to counter the potential smart

attackers in a mobile computing system, without any preliminary knowledge of the environmental parameters and the attack model.

Historical Background

With the proliferation of cloud-based mobile services, mobile devices such as smartphones and tablets can offload their applications and data to the cloud to improve user experience in terms of longer battery lifetime, larger data storage, faster processing speed, and more powerful security services (Xiao et al. 2017). However, data offloading to the cloud via access points (APs) or base stations (BSs) is vulnerable to various types of attacks, such as spoofing, eavesdropping, and jamming (Kumar and Lu 2010). A smart attacker can use smart and programmable radio devices such as Universal Software Radio Peripherals (USPRs) or the Wireless Open-Access Research Platform (WARP) developed by Rice University (Murphy et al. 2006) to throw multiple types of attacks. Compared with traditional single mode attacks, mobile offloading is more vulnerable to smart attacks, as a smart attacker flexibly chooses its attack mode and strength according to the ongoing offloading transmissions and radio environment. For example, a smart attacker can throw jamming attacks if it is close to the serving AP and can efficiently block the offloading or can send spoofing signals with the MAC address of the mobile device.

Although the detection of spoofing and jamming attacks has been well studied (Mukherjee and Swindlehurst 2010; Hu et al. 2015), mobile devices still suffer from time and energy loss due to false alarms and security loss resulting from missed detection of attacks. Security agents at APs or BSs can apply both physical-layer and higher-layer security mechanisms (He et al. 2012) to protect the offloading process. More specifically, the security agent can apply an advanced security mechanism, possibly by processing the offloading data again or changing the session keys, at the cost of higher processing and transmission overhead. The offloading rate of the mobile device is chosen according to the radio

environment, e.g., a mobile device has to process the data locally under strong jamming or heavy traffic at the AP or BS (Yang et al. 2015; Wang et al. 2013; Li et al. 2001; Chen 2015; Xiao et al. 2018c,d).

While game theory has been used to study the interactions between attackers and mobile devices (Mukherjee and Swindlehurst 2010; Hu et al. 2015; Xiao 2015; Xiao et al. 2018a,b,e), mobile offloading usually involves three players: a mobile device, a smart attacker, and a security agent. The secure mobile offloading game is investigated in Xiao et al. (2016), in which a smart attacker can perform multiple types of attacks, including spoofing and jamming, a mobile device determines its offloading rate, and a security agent at the AP protects the offloading with two modes: the fast mode that applies the physical-layer security and the safe mode that applies both the physical-layer and higher-layer security mechanisms. In the dynamic offloading games, a mobile device has difficulty obtaining all the system parameters, such as the channel condition and transmit powers of the attacker in dynamic environments needed to derive the optimal offloading strategy. As an important reinforcement learning technique, Q-learning can be applied by the mobile device to derive the optimal offloading strategy via trials.

Foundations

The secure offloading system consists of a mobile device ($\mathcal{S}$) under the protection of a security agent ($\mathcal{D}$) at the serving access point (AP) and a potential smart attacker ($\mathcal{E}$). The mobile device offloads its applications and data to the cloud via the AP. The offloading rate of the mobile device, denoted by $x \in [0, 1]$, is defined as the proportion of the data that is sent to the serving AP. If $x = 0$, the mobile device processes all the data locally, while $x = 1$ means that all the data are processed in the cloud. The offloading rate is chosen as a tradeoff among the fast processing in the cloud, the radio transmission cost, and the risks of being attacked during offloading.

The smart attacker chooses its attack mode against the mobile device, denoted by $y \in \{0, 1, 2\}$, which corresponds to no attack, spoofing, and jamming, respectively. More specifically, the attacker sends spoofing signals with the mobile device's identity when $y = 1$, transmits jamming signals with jamming power P_E to block the offloading when $y = 2$, and keeps silent when $y = 0$.

The security agent operates in two modes: the safe mode which combines a physical-layer security method such as the channel-based spoofing detector (Xiao et al. 2009) and advanced higher-layer security mechanisms such as the authentication technique presented in He et al. (2012) for attack detection at the AP when $z = 1$ and a fast mode in which only the physical-layer security mechanism is used if $z = 0$. The extra cost of the safe mode over the fast mode denoted by β is positive by definition, and the cost of the fast mode is ignored. Let C_y^z denote the attack cost of the mobile device if the attacker adopts attack mode y and the security agent protects the AP via mode z .

The channel gain between the AP and the mobile device is modeled as a Markov chain. More specifically, the channel gain during the offloading at time n , denoted by $h_T^n \in \mathbf{H}_T = \{H_T^l\}_{1 \leq l \leq N_T}$, is quantized into N_T levels, where H_T^l is the l -th level of the channel gain with $H_T^m < H_T^k, \forall 1 \leq m < k \leq N_T$. The transition probability of the channel gain h_T^n is defined as $p_{m,k} = \Pr(h_T^{n+1} = H_T^k | h_T^n = H_T^m)$. Similarly, the channel gain between the attacker and the AP, denoted by $h_E^n \in \mathbf{H}_E = \{H_E^j\}_{1 \leq j \leq N_E}$, is modeled as a Markov chain with N_E states with transition probabilities denoted by $q_{m,k} = \Pr(h_E^{n+1} = H_E^k | h_E^n = H_E^m)$. For simplicity of notation, the time index of the channel gain is omitted if no confusion results.

It is assumed that both the mobile device and the security agent make decisions to maximize the same utility denoted by u , which depends on the attack mode, the channel gains, and the transmit power of the offloading signals denoted by P_T . Thus, the utility of the mobile device is given by:

$$u(x, y, z) = \begin{cases} x (\log(1 + P_T h_T) - \sigma P_T) - z\beta, & y = 0 \\ x (\log(1 + P_T h_T) - \sigma P_T) - C_1^z - z\beta, & y = 1 \\ x \left(\log \left(1 + \frac{P_T h_T}{1 + P_E h_E} \right) - \sigma P_T \right) - C_2^z - z\beta, & y = 2 \end{cases} \quad (1)$$

where $\sigma > 0$ is the positive unit transmission cost.

In this game, the utility of the attacker denoted by $u_{\mathcal{E}}$ is given by:

$$u_{\mathcal{E}}(x, y, z) = -u(x, y, z). \quad (2)$$

A dynamic mobile offloading game is formulated to model the repeated offloading interactions in dynamic radio environments, which consists of a mobile device, smart attacker, and security agent that are unaware of the system parameters such as the attack cost, the offloading gain, and the current channel condition. Based on Q-learning, the mobile device determines its offloading rate based on the actions of its opponents and the channel condition in the last time slot. To this end, the mobile device observes

the system state denoted by $\mathbf{s}$ at time n given by $\mathbf{s}^n = [y^{n-1}, z^{n-1}, h_T^{n-1}]$. In this game, the offloading rate of the mobile device is quantified into L levels, i.e., $x^n \in \{i/(L-1)\}_{0 \leq i \leq L-1}$ for simplicity.

Let $Q(\mathbf{s}, x)$ denote the quality function of the mobile device for offloading rate x and state $\mathbf{s}$. The value function denoted by $V(\mathbf{s})$ represents the maximum value of the quality function at state $\mathbf{s}$. The mobile device updates its Q-function based on its utility u and the value function as follows:

$$Q(\mathbf{s}^n, x^n) \leftarrow (1 - \alpha) Q(\mathbf{s}^n, x^n) + \alpha \left(u(\mathbf{s}^n, x^n) + \delta V(\mathbf{s}^{n+1}) \right) \quad (3)$$

$$V(\mathbf{s}^n) = \max_x Q(\mathbf{s}^n, x), \quad (4)$$

where $\alpha \in (0, 1]$ is a learning factor indicating the weight of the current estimate of the function Q in the update of the quality function, and the discount factor δ represents the uncertainty of the mobile device about the future rewards.

By applying the ε -greedy policy (Sutton and Barto 1998), the mobile device chooses its offloading rate x^n to maximize its current Q -function with a high probability $1 - \varepsilon$, while the other $L - 1$ rates are taken with equal probability, i.e.,

$$\Pr(x^n) = \begin{cases} 1 - \varepsilon, & x^n = \arg \max_x Q(s^n, x) \\ \frac{\varepsilon}{L-1}, & o.w. \end{cases} \quad (5)$$

Key Applications

Learning-based secure mobile offloading strategy provides the mobile device with intelligent defense mechanism against smart attacks in the mobile computing system, which balances the security performance and the energy consumption of the devices by adjusting the offloading data rate and the defense mode. Even without knowing the environmental parameters, the mobile devices can apply it to derive the optimal policy to improve the secure data communication efficiency via trial and errors.

Definitions

Lens antenna array refers to a special category of antenna arrays in millimeter wave multiple-input multiple-output (MIMO) systems. The most distinguishing characteristic of lens antenna arrays is that there is an electromagnetic lens placed between the antenna array and the coming direction of wireless signals. Intuitively, the lens antenna arrays focus the signals from a certain spatial direction onto a particular antenna element. From the perspective of signal processing, the function of the electromagnetic lens can be interpreted as a phase shifting network, which transforms the spatial MIMO channel into the beamspace channel.

Historical Background

Lens antenna array is proposed very recently, mainly coming with the research on millimeter wave MIMO systems. The earliest representative work on lens antenna array that could be found in literature was conducted by A. M. Sayeed and J. Brady from University of Wisconsin, Madison, in

2013 (Brady et al. 2013). In (Brady et al. 2013), the authors built a general computational framework for MIMO systems with lens antenna arrays (namely, beamspace MIMO systems), based on which the link capacity was analyzed. To verify the accuracy of their models, authors in (Brady et al. 2013) also compared results from theoretical analysis and prototype measurements, where a fairly high consistency was observed. Following their work in (Brady et al. 2013), A. M. Sayeed's group has continued to generalize the initial work in single-user line-of-sight scenario to multipath (Song et al. 2013) and multiuser scenario (Brady and Sayeed 2014).

Shortly after (Brady et al. 2013), another group from National University of Singapore also published their work on lens antenna array (Zeng et al. 2014, 2017; Zeng and Zhang 2016), where more emphasis have been put on the transmission scheme design in MIMO systems with lens antenna arrays. In (Zeng et al. 2014), Y. Zeng and R. Zhang applied an electromagnetic lens enabled beamspace MIMO system in a single-cell multiuser uplink scenario. A new path division multiplexing (PDM) paradigm has been proposed in (Zeng and Zhang 2016) based on the beamspace MIMO, where different data streams are transmitted over different paths. Furthermore, Y. Zeng and R. Zhang continued to generalize the single-user PDM paradigm to the multiuser case under the framework of path division multiple access (PDMA) in (Zeng et al. 2017).

More recently, various studies on MIMO systems with lens antenna arrays have sprang up. Though MIMO systems with lens antenna arrays can achieve obvious performance gains, such gains are highly dependent on accurate channel state information (CSI) at transceivers. To address the CSI acquisitions issue, X. Gao et al. in 2017 proposed a compressive sensing-based channel estimation approach with low pilot overhead and high accuracy. To improve the spectral efficiency of the system, B. Wang et al. in 2017 investigated the combination of MIMO systems with lens antenna array and non-orthogonal multiple access (NOMA) techniques, i.e., beamspace MIMO NOMA. Compared with conventional beamspace MIMO, beamspace MIMO NOMA is able to serve multiple users

simultaneously in the same beam, which can obviously improve the achievable sum rate of the system.

Foundations

Lens antenna arrays are usually utilized in the high-frequency band MIMO systems (e.g., millimeter wave (mmWave) MIMO or Tera Hz (THz) MIMO), to reduce the signal processing dimensions. In high-frequency band communications, MIMO techniques with large-scale antenna arrays are usually utilized to compensate the severe propagation loss. However, as the number of antennas in MIMO systems increases, it is very challenging to operate key signal processing procedures such as precoding and channel estimations. The most prominent reason for this problem is that the conventional fully digital transceiver architecture requires one dedicated radio frequency (RF) chain (including high-resolution digital-to-analog converters) for each antenna. Such configuration brings prohibitively high energy consumption and hardware cost, since the RF chains will be power-hungry and costly in the mmWave and THz frequency.

Intuitively, the function of lens antenna arrays can be interpreted as focusing the signal coming from each path onto a certain antenna element. From the perspective of signal processing, the lens antenna arrays perform a uniform spatial Fourier transformation on the channel, i.e., transfer the conventional spatial MIMO channel into the beamspace channel. In the beamspace channel, each channel element corresponds to the gain of one path toward certain direction. Thanks to the limited scattering characteristics in mmWave or THz signal propagations, the beamspace channel presents an obvious sparse structure. Basically, only those channel elements with obvious power need to be selected. In other words, the communication in beamspace channel only occurs in a subspace, which indicates that the dimension of MIMO systems can be much reduced.

The dimension reducing ability of lens antenna arrays mainly depends the sparsity level

of the beamspace channels, i.e., the number of available paths in signal propagations. This explains why lens antenna arrays are more suitable for high-frequency communications, where the number of paths is usually small due to the high path loss. In lower frequencies (e.g., sub-6 GHz) where the channel demonstrates a denser scattering, using lens antenna array will hardly reduce the system dimensions.

Key Applications

Lens antenna arrays are usually utilized in the high-frequency band MIMO systems to reduce the system dimensions. With a lower dimension, the enormous energy consumption and hardware cost due to huge RF networks or phase shifter networks can be greatly saved.

Definitions

Primary network refers to a wide-area wireless access network provided by mobile communication companies or other ISPs, such as 3G, 4G, etc.

Secondary network refers to a short-range device-to-device connections such as Wi-Fi Direct, Bluetooth, NFC, etc.

Historical Background

In recent years, the capacity of mobile devices, including both networking and computational, has been kept improving. However such development still falls short when facing increasing requirement from various kind of new services developed.

To address such inconsistency, the term “cloud” has been proposed and swiftly popularized in both academia and industry. Cloud off-loads a great deal of computational tasks from mobile devices to a group of powerful servers remotely located. Cloud enables low-capacity devices to perform computational-intensive tasks, by trading-off precious bandwidth resources and potentially long delay.

It is often the case that a mobile device’s task is only valid and useful locally, i.e., within a small proximity of the device. Therefore, those tasks are best performed at the device end. With the development of mobile peer-to-peer connectivity, Mobile devices are now able to connect with each

other to form a high-speed wireless P2P network at the edge to perform computational-intensive tasks by sharing their resources.

Among those tasks, one promising type is video live streaming. With the development of video formats, a single device can rarely stream a high-quality (e.g., high definition, high frame rate, etc.) video with stable and satisfactory quality. For regionally popular videos, it is possible that a group of nearby mobile devices interested in the content form a P2P network and collaboratively complete the streaming and sharing task.

Introduction

With the advances in multimedia capability of wireless devices, live video streaming to handheld devices has become a reality. Conventional streaming approaches utilize the client-server model, in which each mobile station (MS) independently *pulls* streams from the server

via an access point (AP) or base station (BS). However such approach suffers from several limitations including low scalability and coverage blind spots.

To overcome the above limitations, wireless cooperative streaming has been proposed. This is motivated by the much success of peer-to-peer (P2P) streaming over the Internet. In wireless P2P streaming, devices form a wireless multihop network and cooperatively exchange video data with each other to achieve efficient stream broadcasting. This architecture is becoming possible by the fact that more and more wireless devices nowadays are equipped with not only multiple wireless interfaces (e.g., 3G, Wi-Fi, and Bluetooth) as well as antennas but also large memory and high processing capabilities.

Figure 1 shows the network considered for mobile P2P live streaming, where dashed lines indicate the underlay connectivities. There is at least one *source node* in the network who either generates video content or gets it from the streaming server via a long-range *primary* channel such as a 3G or 4G network. The sources then share the data with their neighbor via a *secondary* channel. The receiving nodes then further share their content to their neighbors.

Such a cooperative wireless live video streaming network needs to be efficient in that given limited resources, it needs to achieve good service quality. More specifically, the network needs to be efficient in the following aspects:

- *Optimized overlay* The streaming overlay needs to be efficient in terms of low control overhead and low traffic redundancy given sufficient user coverage, irrespective of the network dynamics.
- *High playback quality* Video distortion at the client side is an important QoS metric for video streaming. Given limited resources, the streaming network should deliver video stream to users with high playback quality.
- *Efficient loss recovery* Packet loss is inevitable in wireless video streaming due to dynamic channel condition. These losses must be recovered with low recovery traffic.

Live Video Streaming in Wireless P2P Networks, Fig. 1 Mobile peer-to-peer network in consideration. A subset of mobile devices requests video stream from content server via primary channel through access point/base station and then share their stream with nearby neighbors via a secondary channel

To understand how the above discernment may be achieved, the characteristics of wireless multihop network need to be first reviewed. Wireless multihop network bears the following distinctive characteristics:

- *Broadcast nature* Each wireless transmission will be overheard by neighbors within range. This broadcast nature brought several unique properties including high transmission efficiency, high loss recovery efficiency, high spatial diversity and loss recovery efficiency (Li et al. 2013), per-hop media contention, and potentially high interference/delay.
- *Network dynamicity* Wireless multihop network is dynamic due to peer churn, making schemes designed for relatively static networks not applicable.
- *Scarce network resource* Network resources in wireless environment, including mainly device computational power, network bandwidth, and device energy, are often severely limited and cannot afford the high control overhead as in wired P2P.
- *Limited “parent” candidates* In wireless environment a client can only get supplied from a few neighboring nodes.
- *Different natures of loss* Losses in wireless network are generally not caused by congestion as in wired network, but rather due to signal errors as a result of noise, interference, or transient disconnection. In this case the congestion avoidance mechanisms such as the one used in TCP will only harm the effective throughput.

In the remainder of this chapter, the aforementioned three properties of a wireless multihop streaming network will be discussed, with proposed approaches addressing them introduced.

Overlay Optimization

Appropriate overlay design crucially affects the performance of the streaming network. Wireless P2P overlays generally fall into one

of three major categories, namely, unstructured, structured, and hybrid overlays, based on whether transmissions follow predetermined routes.

The main characteristic of an **unstructured overlay** is that the routing of each data piece is determined independently on the fly at each hop. The motivation is primarily its ability of dealing with network dynamics, as well as its simplicity and distributed nature. An efficient mesh-based mobile P2P live streaming protocol called **COSMOS** has been proposed in Leung and Chan (2007). In COSMOS a small number of mobile peers pull a video description from the server via an AP, and then each determines whether to push the content to its neighbors. The heuristic applied is the fraction of puller’s one-hop neighbors that could benefit from such rebroadcast. Discovering and selecting *partner set* are proposed in **P2PMLS** (Jinfeng et al. 2007). A new joiner first checks if there is any neighbor peers or multihop nodes receiving the same data. If such neighbors are found, a subset of them is chosen to be stream suppliers. Otherwise the peer becomes a puller itself. The works in Wu and He (2011) introduces *preference score* of a neighbor node, which measures the mobility pattern similarity as well as the load of the neighbor node. *Tendency score* is also proposed to quantify the “tendency” that a neighbor may become a good supplier. Li et al. proposed a distributed scalable video (SVC) multicast algorithm that jointly optimizes video quality and network traffic (Li et al. 2012). The scheme finds multiple disjoint paths and a backup path for each destination. Another similar optimized flow selection algorithm is proposed in Abdel Khalek and Dawy (2012).

In **structured overlay**, a broadcast spanning tree is continuously maintained so that the routes to all the clients via this tree are readily available for streaming. The major advantage of such proactive, tree-based overlay construction is its shorter routing delay and less redundant transmissions. However, a higher control overhead is normally required and the overlay continuously updated due to network dynamics, even when there is no data.

In single-tree overlay construction, mobile nodes form a broadcast tree spanning all the nodes. Much research work on mobile P2P streaming are single-tree based. Chen and Kao in (2013) employs a game-based parent selection algorithm called **GB-BTC** for tree construction. Each node in GB-BTC will prefer to select the neighbor node with maximum number of children as well as low expected transmission counts (ETXs) as its parent. Recently, Chang et al. in (2014) proposed **PNCB** to build a broadcast tree for each video broadcasting source. The work suggests that the number of transmissions required at any node is lower bounded by the maximum number of trees that select a common outgoing link from this node. Consequently, a neighboring node is preferred to be the parent if doing so does not increase the neighbor's max out-degree.

In single-tree approach, leaf nodes often suffer from high loss due to error propagation and the delay between unexpected disconnections and subsequent parent renegotiations. Multi-tree approach tries to address this by constructing multiple trees for concurrent use. It usually makes use of multiple description coding (MDC) or scalable video coding (SVC) and constructs multiple trees each for a description/layer of the video.

Hybrid overlay topology, often referred to as structured mesh, is to combine the strengths of both unstructured mesh approach and tree approach. Two types of hybrid architectures are introduced, namely, interleaved hybrid and tiered hybrid (Kubo et al. 2010). Interleaved hybrid topology tries to add additional links over a tree structure. Tiered hybrid topology constructs a tree with high relay-ability nodes, which supports the mesh network formed by the rest of the nodes.

Another hybrid topology, called **Local-Tree** (Zhang et al. 2011), aims at optimizing an unstructured *mesh* with regional tree structures. In LocalTree, new joiners initially form an unstructured mesh. Relatively stable node groups (based on link transmission success rate and node relay probability) are identified distributedly. Within each node group, a locally optimized tree is computed.

Packet Loss Recovery

In wireless video broadcasting, packet loss often occurs due to the dynamic nature of wireless channel (i.e., random bit errors, burst errors, or transient outages). Timely loss recovery is hence important to achieve good service quality. In the traditional approach, a mobile station (MS) with packet loss, the so-called *errored MS*, requests the server for retransmission via a separate backward channel. There has been much work on server retransmission-based error recovery for wireless video by feeding back loss information to the server (Chachulski et al. 2007; Schier and Welzl 2012). A common assumption for all the above work is a feedback channel to the server, so that ACKs or NAKs can be reported back to trigger retransmission at the server. This is not scalable to a large pool of MSs due to the bandwidth limitation of the wireless channel and at the server.

With the development of network coding (NC), another approach lets the server perform network coding on source packets and broadcast coded packets to clients. This approach requires the knowledge of network loss condition and is often designed for certain worst-case loss. There have been many erasure-resilient coding algorithms studied, such as Reed-Solomon code and fountain codes (e.g., Tornado code, Raptor code, or Luby transform (LT) code). Much work has been done using FEC to recover errors (Lee et al. 2011; Nguyen et al. 2011). FEC is normally designed for a certain worst-case loss rate, which uses bandwidth unnecessarily in a low-loss condition and is insufficient to recover loss in a high-loss condition.

Given that nowadays MSs are often equipped with a (free) secondary broadcast channel (e.g., Wi-Fi or Bluetooth), such channel may be used for cost-effective cooperative error recovery. Cooperative loss recovery has been studied in Alnuweiri et al. (2012); Liu et al. (2015). Source packet sharing is adapted in most of these works, reducing the recovery effectiveness. In many proposed NC-based approach, cooperative recovery is *unicast* based, limiting the effectiveness of recovery packets to a single receiver.

With the above insights and inspired by Liu et al. (2011b), the authors proposed **BOPPER** in Zhang et al. (2014), which combines broadcast-based cooperative recovery with linear network coding. BOPPER is therefore adaptive to heterogeneous loss rates. It is complementary to FEC and can be applied *after* FEC to reduce transmission overhead and to achieve lower residual loss rate. In BOPPER, a node generates parity packets based on the possibly partial group of source packets received. When the number of received parity packets received from other peers is no fewer than the number of lost source packets, these source packets can be recovered with very high probability. An MS generates parity packets based on the error status of its neighbors, and hence the number of parity packets generated by an MS adapts local loss condition. An MS may generate parity packets based on the source packets it received via the primary channel. Furthermore, by employing NC for local error recovery, MSs with different losses may use the same parity packets for recovery, which effectively reduces recovery traffic in the secondary channel. Neighboring nodes inform each other by broadcasting NAK messages periodically. In order to reduce control overhead, NAK further proposes NAK suppression, so that latter NAKs can be safely suppressed if the information is contained by earlier ones.

Bandwidth Utilization

Novel video formats, such as VR, AR, 360 video, and free-viewpoint video (FVV), enable new and compelling viewing experience (Liu et al. 2011a). In an implementation of FVV, *anchor views* of a scene are captured simultaneously in texture-plus-depth format by a discrete array of cameras. A user receiving some of these anchors may either play back an anchor or render a *virtual view* (i.e., views not captured by any camera) given his/her available anchors using depth-image-based rendering (DIBR).

In this section, a group of wireless users interested in a live FVV is considered. They pull the anchor streams from a remote server (through, e.g., 4G data network). As wireless bandwidth is precious, how to efficiently utilize the bandwidth to provide the best possible received video quality to the users becomes a challenging problem. One simple approach is that, upon each view switch at a user, the server renders the requested view for the user. In Miao et al. (2011), a cloud is employed to compute and render each requested view. The work in De Raffaele and Debono (2010) studies view-switching prediction to reduce traffic and computation load at the server for each view switch.

Streaming all the anchors to users for them to render all the views they need would consume prohibitively large server and network bandwidths. Streaming only a subset of anchors to each user may lead to severely degraded video quality due to increased anchor distances. To address this issue, network coding and cooperative sharing techniques may be utilized. The work termed **PAFV** in Zhang et al. (2016) considers the scenario where clients collaboratively pull anchors and share NC packets formed by the pulled anchors. Given the distortion function and spatial popularity, PAFV optimizes anchor pulling and NC generation in each client, in order to minimize the overall expected video distortion, subject to bandwidth constraints. PAFV employs a max-clique algorithm to solve the anchor sharing problem.

Conclusion

The broadcast nature of wireless transmissions and topology dynamics of wireless cooperative networks bring challenges to the overlay design of a P2P streaming system over such a network. Different types of overlay designs, namely, unstructured, structured, and hybrid approaches are discussed. In order to repair the lost packets in wireless video broadcasting, efficient cooperative loss recovery schemes are reviewed. For new video paradigms such as 360 video, VR

video, and free-viewpoint video, efficient streaming schemes are checked and discussed.

Load Balancing in Data Center Networks

Synonyms

DCN traffic scheduling

Definitions

Load balancing uses advanced multilayer switching technology to provide real-time monitoring of server performance and health (Zhang et al. 2018). According to the health of different servers, the data traffic of the visitor is allocated to the appropriate server in the most economical and efficient manner. In this way, the load of each server can reach a relative balance, so that the resource sharing of the relevant data receiving device is optimal, the response time is short, the processor runs faster, the data exchange amount is greatly improved, and the operation efficiency is qualitatively leap.

Load balancing of data center networks usually involves two application scenarios. One is to evenly allocate large-scale concurrent access or network traffic to multiple server nodes to implement multiple servers responding to requests from different users. Another is to allocate the large-scale computational unit load evenly to multiple server nodes for arithmetic processing and then aggregate the operation nodes to feed back the user results.

Historical Background

With the rapid development of Internet technology and the widespread use of communication devices, the number of Internet users has increased rapidly, and the amount of data on the network has also increased dramatically. It can be said that data has entered an era of explosive growth. Therefore, new technologies are needed to store and process such large-scale data, and data center networks are put forward in this context.

The data center network refers to the network infrastructure of the data center, which connects a large number of servers through high-speed links and switches (Guo et al. 2008). The traditional data center network uses multiple tree topologies and consists of two or three layers of switch fabrics that can accommodate thousands of servers. However, in recent years, emerging

information services require a large amount of communication between virtual machines and servers, resulting in a sharp increase in Internal traffic in the data center and also presenting a new feature that is different from Internet traffic. Traditional tree-based data center architectures exhibit some shortcomings such as poor scalability, low utilization of network resources, and fragmentation of resources.

Therefore, academia and industry have begun to design new types of data center networks structures. Currently, there are two main types. One is a switch-centric structure and switches are used to exchange forwarding data, such as fat-tree (Greenberg et al. 2008) and Monsoon (Mysore et al. 2009). The other is a server-centric structure that uses servers to exchange forwarding data, such as BCube (Guo et al. 2009), DCeli, MDCube (Wu et al. 2009), etc. They make up for the shortcomings of the traditional tree-based data center networks structure from different aspects. Among them, the fat-tree topology is relatively simple and easy to deploy. At the same time, it also improves the problems of poor scalability, low utilization of network resources, and excessive load on the core layer switches in the traditional tree-based structure.

Foundations

In order to fully utilize the bandwidth resources in the network, the data center should employ the corresponding load balancing technology. By adaptively allocating the traffic among nodes throughout the network, the bandwidth utilization on different paths will be dynamically balanced in order to maximize the throughput of long data streams.

The traditional data center network adopts ECMP (equal-cost multipath) technology as the load balancing mechanism. Generally, the polling algorithm, the greedy algorithm, and the hash algorithm are used to evenly allocate the traffic load to multiple equal paths. That is, there are multiple paths between the source switch and the

destination switch to transmit data packets. The source switch distributes the traffic destined for the destination switch to multiple paths according to a load balancing algorithm, so that each path carries a part of the traffic and each path can be fully utilized. Therefore, it can avoid the use of only one path, which causes the network congestion, packet loss, and network throughput drop. However, due to its simplicity, the performance is greatly constrained.

How to optimally distribute ECMP traffic has always been a hot topic in academic fields. In order to solve the shortcomings of traditional ECMP, many adaptive dynamic load balancing techniques have been proposed. These technologies can be divided into three categories according to different mechanisms: centralized load balancing technology, switching device-based load balancing technology, and host-based load balancing technology.

Centralized Load Balancing Technology

Centralized load balancing technology relies on a centralized controller or host to specify the transmission path of the data stream. Typical centralized technologies, such as Hedera and Mahout, all take advantage of the idea of software-defined networking (SDN). They separate the pathfinding strategy and mechanism of the data stream, control the path of the data stream through centralized node control, and then dynamically update the routing table to achieve dynamic load balancing.

The centralized load balancing technology can effectively collect the link states of the entire network and determine the globally optimal load scheduling policy through calculation. At the same time, the centralized solution can also effectively deal with the fault paths that often occur in the network, making the scheduling strategy highly robust. However, the data center short data stream accounts for more than 80% of the total number of all data streams. The centralized load balancing technology is difficult to handle a large number of short data streams, so it is inevitable to face scalability and single point of failure problems. The biggest bottleneck of the load balancing technology is that the interaction

between the controller and the node takes a lot of time, which limits its development.

Switching Device-Based Load Balancing Technology

Unlike centralized load balancing technology, load balancing based on switching devices deploys the entire traffic scheduling function on switching devices in the network. Typical representations of such techniques are PacketScatter, LocalFlow, DRB, and CONGA.

Host-Based Load Balancing Technology

In order to make up for the shortcomings of centralized technology, many scholars have proposed a data center networks load balancing technology based on the host. This type of technology can operate without any centralized control. It uses the terminal system to detect the transmission status and link status in the network, calculates the appropriate routing path in the terminal system, and implements the scheduling control of the load through the source routing mechanism. Typical host-based load balancing technology includes MPTCP, FlowBender, and Presto.

Key Applications

It can be seen from the load balancing algorithms of the existing data center networks that the network architecture is very different in different scenarios, which also leaves a lot of redesigned space for the new scenarios. There are many new technologies, such as machine learning, that are deployed in data centers, and the emergence of these technologies may change the design of load balancing mechanisms.

Localization of wireless sensor networks deployed over complex 3D terrains

Problem Definition

Sensor network localization refers to the process of estimating the locations of sensor nodes with information between neighboring sensor nodes such as connectivity, local distance, and angle measurements. In real-world applications, many large-scale wireless sensor networks (WSNs) are deployed over complex terrains. Formally, a three-dimensional (3D) surface WSN is defined as follows.

Definition 1 (3D Surface Wireless Sensor Network) A 3D surface sensor network consists of sensor nodes deployed on a 3D surface where wireless signals between nearby nodes propagate along the surface only.

Definition 2 (Localization of 3D Surface Wireless Sensor Network) Given a 3D surface sensor network with distance measurements between neighboring nodes within their communication range, the localization problem is to recover the 3D coordinates of each sensor node.

Historical Background

Localization of a network deployed over a 3D surface generates a unique hardness compared with the well-studied localization of a network on 2D plane or in 3D volume. Specifically, due to limited radio range, the distance between two remote sensors deployed over a 3D surface can only be approximated by their surface distance, the length of the shortest path between them on the surface. Such surface distance is different from the 3D Euclidean distance of two nodes. A 3D surface is *localizable* if it exists a unique embedding up to a global rigid motion, under given constraints. Otherwise it is *non-localizable*. The following theorem claims that a network deployed over a 3D surface with surface distance information only is non-localizable, even if we assume accurate range distance measurement available (Zhao et al. 2012).

Theorem 1 *A general 3D surface is not localizable, given surface distance constraints only.*

One intuitive example is that a piece of paper shown in Fig. 1a can be rolled up to a cylinder illustrated in Fig. 1b or to other curved shapes (see Fig. 1c). The distances between all pairs of points on the paper clearly remain the same under different shapes. Besides the open surface discussed above, similar deformation can be applied on closed surfaces (see Fig. 1d–f for example). Clearly, ambiguous embeddings exist, and thus a general 3D surface is not localizable under given surface distance constraints only.

Given a wireless sensor network deployed on a 3D terrain surface with one-hop distance information available, a simple distributed algorithm introduced in Zhou et al. (2011) extracts a refined triangular mesh from the network connectivity graph. Vertices of the triangular mesh represent the set of sensor nodes. An edge between two neighboring vertices indicates the communication link between the two sensors. The state-of-the-art surface network localization methods are based on the extracted triangular mesh structure.

Surface Network Localization with Height Information

Under a practical setting with estimated link distances (between nearby nodes) and nodal heights (i.e., Z-coordinates) obtained by measuring atmospheric pressure, a sensor network deployed on a single-value 3D surface is localizable. Briefly, a single-value surface is one on which any two points have different projections on the X-Y plane. The definition is in reference to X-Y plane since sensors' heights are given as Z-coordinates. A planar projection of network deployed on a single-value surface converts a surface network localization problem to a planar one. The X-Y coordinates of nodes can be computed with well-known planar localization algorithms (Shang et al. 2003; Shang and Ruml 2004; Vivekanandan and Wong 2006; Lim and Hou 2009; Jin et al. 2011). The localization result is then mapped back to 3D by adding the known Z-coordinates.

For sensor networks deployed on general 3D surfaces, a distributed localization algorithm, dubbed cut-and-sew, applies a divide-and-

Localization in 3D Surface Wireless Sensor Networks, Fig. 1 Illustration of the non-localizability of general 3D surfaces. A surface can be deformed to another one without changing the surface distance between any pair

of points. (a) A 2D surface. (b) Deform to cylinder. (c) Deform to wave shape. (d) A closed 3D surface. (e) Small deformation. (f) Large deformation (Zhao et al. 2012)

Localization in 3D Surface Wireless Sensor Networks, Fig. 2 An overview of the cut-and-sew algorithm for general 3D surface localization. (a) A 3D surface network. (b) Triangular mesh. (c) Identified non-single-value edges.

(d) Partition of network to single-value patches. (e) Localization of individual patch. (f) Final localization result (Zhao et al. 2013)

conquer approach to localize sensor nodes with height information available. The basic idea is to partition a general 3D surface network into single-value patches, localizing individual patch and then merging them into a unified coordinate system. Note that the number of single-value patches should be minimized to avoid unnecessary partitioning and merging, which are subject to linear transformation errors. The key is to identify non-single-value edges that guide the division of a 3D surface network into single-value patches.

Figure 2 illustrates the basic idea of the cut-and-sew algorithm. Specifically, Fig. 2a, 2b shows a sensor network and the extracted triangular mesh, respectively. An edge is locally non-single-value if the projection of its two associated triangles overlaps on the X-Y plane. Each node in the network performs a simple and localized scheme to determine whether an associated edge is a non-single-value one based on its local distance information. Figure 2c shows the identified non-single-value edges. A set of non-single-value edges form the boundary of a single-value patch. Figure 2d illustrates the partition of network into a minimum set of single-value patches. Each single-value patch can then be localized as shown in Fig. 2e. Since neighboring patches share common vertexes and

edges, they can be readily “sewed” together and yield a unified coordinate system for the entire 3D surface sensor network as illustrated in Fig. 2f.

Under practical sensor network settings, both surface distances and sensors heights are subject to measurement errors. The noisy distance and height measurements directly affect the identification of non-single-value edges, which may deviate from the ground truth and become isolated. One approach is to fuse nearby non-single-value edges to form a band and then cut the network along the medial axis of the band. This method effectively minimizes the impact of input errors on network partition and localization.

Prototyping and Experiments

Figure 3a shows one indoor test bed model built for prototyping 3D surface sensor networks with 5.25 feet high, 3 feet long, and 3 feet wide. Forty-eight Crossbow MICAz motes are attached to its surface. The algorithmic codes are implemented in Tiny OS and run on the Crossbow sensor nodes. The sensors are configured to use close to minimum radio transmission power (level 2) with a communication range between 25 and 55 cm. The short radio range avoids undesired connections through volume.

Every sensor periodically broadcasts a beacon message that contains its node ID to its

Localization in 3D Surface Wireless Sensor Networks, Fig. 3 Experimental setup and result. (a) Indoor 3D surface network test bed. (b) Input triangulation. (c)

Localization result (with an average location error of 14%) (Zhao et al. 2013)

neighbors. Based on received beacon messages, a node builds a neighbor list with the RSSI of corresponding links. RSSI is used to estimate the length of links by looking up a RSSI-distance table established by experimental training data. The preliminary test shows that, under low transmission power, such estimation has an error rate about 20%. At the same time, the ground truth of surface distances and sensor coordinates is manually measured. Figure 3b illustrates the triangulation based on ground truth inputs. Figure 3c shows the localization result. The combined patches largely restore the original 3D surface network, with an average location error of about 14%.

Surface Network Localization with Digital Terrain Model

Integrating height measurement into every sensor of a network is not always practical and affordable, especially for a large-scale sensor network. However, a 3D representation of a terrain's surface, called digital terrain model (DTM), is available to public with a variable resolution up to one meter. DTMs are commonly built using remote sensing technology or from land surveying. A DTM is represented as a grid of squares, where the longitude, latitude, and altitude (i.e., 3D coordinates) of all grid points are known. It

is straightforward to convert a grid into a triangulation, e.g., by simply connecting a diagonal of each square. Therefore a triangular mesh of a terrain surface can be available before we deploy a sensor network on it. On the other hand, a refined triangular mesh can be extracted from the connectivity graph of network deployed on the terrain surface with local distance information. The constraint that the sensors must be on the known 3D terrain surface ensures that the triangular meshes of terrain surface and network approximate the same geometric shape. Theoretically, the two triangular meshes share the same conformal structure. We can construct a well-aligned conformal mapping between them. Based on this mapping, each sensor node of the network can easily locate reference grid points of the DTM to calculate its own location.

Figure 4 illustrates the basic idea to localize a surface network on a 3D terrain surface with DTM available. Figure 4a, c shows the triangular meshes of a terrain surface and a network deployed over the terrain surface, respectively. We first compute two conformal mappings, denoted as f_1 and f_2 respectively, to map the two triangular meshes to plane as shown in Fig. 4b, d respectively. However, the two mapped triangular meshes on plane are not aligned. Three anchor nodes, sensor nodes equipped with GPS, marked with red as shown in Fig. 4c are deployed with the network to provide a reference for alignment.

Localization in 3D Surface Wireless Sensor Networks, Fig. 4 (a) The triangular mesh of a terrain surface. (b) The triangular mesh of the terrain surface is conformally mapped to plane. (c) The triangular mesh of a network

deployed on the terrain surface with three randomly deployed anchor nodes marked with red. (d) The triangular mesh of the network is conformally mapped to plane (Yang et al. 2014)

Localization in 3D Surface Wireless Sensor Networks, Fig. 5 The first row shows a set of DTMs of representative terrain surfaces. The second row shows sensor nodes marked with black points randomly deployed on these

terrain surfaces. The third row shows the localized sensor networks with anchor nodes marked with red (Yang et al. 2014)

Based on the positions of the three anchor nodes, we construct a Möbius transformation, denoted as f_3 , to align the mapped triangular meshes of the network and the terrain surface on plane. Combining the three mappings, $f_1^{-1} \circ f_3 \circ f_2$, induces a well-aligned conformal mapping between the two triangular meshes shown in Fig. 4a, c, respectively. Based on the well-aligned mapping, each sensor node of the network simply locates its nearest grid points, vertices of the triangular mesh of the terrain surface, to calculate its own geographic location.

Deployment of Anchor Nodes

Figure 5 shows a set of representative terrain surfaces and their corresponding DTMs, on which sensor nodes marked as black points are randomly deployed. For each network, eight tests are repeated with a various deployment of three anchor nodes in each test. Table 1 shows the mean (μ), median ($\tilde{x}$), and standard deviation (σ) of localization errors under different deployments of anchor nodes of each network. The positions of three anchor nodes affect the performance of the localization algorithm slightly. In general,

Localization in 3D Surface Wireless Sensor Networks, Table 1 The distribution of localization errors under different sets of anchor nodes (Yang et al. 2014)

Error	DTM I	DTM II	DTM III	DTM IV
μ	0.2579	0.1356	0.0951	0.2098
$\tilde{x}$	0.2306	0.1343	0.0956	0.1512
σ	0.1089	0.1717	0.0158	0.0352

Localization in 3D Surface Wireless Sensor Networks, Fig. 6 Localization error decreases slightly with the increased number of anchor nodes (Yang et al. 2014)

the more scattered the three anchor nodes are deployed in a network, the lower the localization error is.

Size of Anchor Nodes

Theoretically speaking, the localization algorithm requires only three anchor nodes to align two triangular meshes on plane, regardless of the size of a network. If more anchor nodes are deployed on the network, a least-square conformal mapping method can replace Möbius transformation to incorporate all anchor nodes into the alignment to improve the localization accuracy. Figure 6 shows one example. The localization error of a network with size 2.6 k deployed on a 3D surface, shown in Fig. 4d, decreases slightly with the increased number of anchor nodes.

Applications

Geographic location information is imperative to a variety of applications in WSNs, ranging from position-aware sensing to geographic routing. While global navigation satellite systems (such as GPS) have been widely employed for localization, integrating a GPS receiver in every sensor of a large-scale sensor network is unrealistic due to high cost. Moreover, some application scenarios prohibit the reception of satellite signals by part or all of the sensors, rendering it impossible to solely rely on global navigation systems. In real-world applications, many large-scale WSNs are deployed over complex terrains, such as the volcano monitoring project (Werner-Allen et al. 2006). The introduced state-of-the-art surface network localization algorithms recover the coordinates of sensor nodes with assumption of the availability of nodal height measurements (Zhao et al. 2012, 2013) or digital terrain model, a 3D representation of terrain’s surface (Yang et al. 2014). They are all distributed and scalable to large-scale sensor networks deployed over general 3D terrain surfaces.

Definitions

This entry provides information about the ad hoc net-based LBS, including the histories, the positioning principles, the classical strategies, and the key applications.

Historical Background

In 1997, Ward et al. (1997), Welch et al. (1999), and Priyantha et al. (2000) proposed localization systems rely on beacons. All beacon-based positioning algorithms, however, have their limitations because they need another positioning scheme to bootstrap the beacon node positions. Therefore, in 2004, beacon-free algorithms were proposed in Shang and Ruml (2004), Ji and Zha (2004), and Priyantha et al. (2003). Beacon-free algorithms utilize local distance information rather than beacons to estimate the relative coordinates of each node.

In 2002, a signal strength decay-based ranging scheme was implemented in Patwari et al. (2002). This work belongs to range-based localization. In contrast, range-free algorithms do not require distance estimation or angle estimation. For example, connectivity matrix of sensor nodes can be used for position estimation (Doherty et al. 2001); the Euclidian distance estimated by hop-count can be used to estimate the node locations via triangulation method (Niculescu and Nath 2003; Nagpal et al. 2003). Incremental algorithms are used in ad hoc network positioning. At the beginning, only three or four core nodes are located, and then more nodes are located based on the positions of the core nodes (Savarese et al. 2001). However, incremental algorithms have error propagation problem, resulting in poor overall performance. Concurrent strategies are invented to solve this problem, all nodes are approximately located at the beginning, and then the node positions would be optimized based on the node-to-node distances (Priyantha et al. 2003).

Basic Positioning Principles (Liu et al. 2007)

Triangulation

Triangulation uses the geometric properties of triangles to estimate the target location. It has two derivations: ranges and angulation. Range estimates the position of an object by measuring it from multiple reference points. So, it is called range measurement techniques. Instead of measuring the distance directly using received signal strengths (RSS), time of arrival (TOA) or time difference of arrival (TDOA) is usually measured, and the distance is derived by computing the attenuation of the emitted signal strength or by multiplying the radio signal velocity and the travel time. Roundtrip time of flight (RTOF) or received signal phase method is also used for range estimation in some systems. Angulation locates an object by computing angles relative to multiple reference points.

Ranging Techniques

- TOA: The distance from the mobile target to the measuring unit is directly proportional to the propagation time. In order to enable 2-D positioning, TOA measurements must be made with respect to signals from at least three reference points, as shown in Fig. 1 (Kim et al. 2016a).

Location Based Service of Ad Hoc Networks, Fig. 1
Positioning based on TOA/RTOF measurements

For TOA-based systems, the one-way propagation time is measured, and the distance between measuring unit and signal transmitter is calculated. In general, direct TOA results in two problems. First, all transmitters and receivers in the system have to be precisely synchronized. Second, a timestamp must be labeled in the transmitting signal in order for the measuring unit to discern the distance the signal has traveled. TOA can be measured using different signaling techniques such as direct sequence spread-spectrum (DSSS) (Liu et al. 2014; Ye et al. 2016) or Ultra Wide Band (UWB) measurements (Zadgaonkar and Chandak 2016). A straightforward approach uses a geometric method to compute the intersection points of the circles of TOA. The position of the target can also be computed by minimizing the sum of squares of a nonlinear cost function, i.e., least-squares algorithm (Kim et al. 2016a; Gu et al. 2017). There are other algorithms for TOA-based location system such as closest-neighbor (CN) and residual weighting (RWGH) (Gu et al. 2017). The CN algorithm estimates the location of the user as the location of the base station or reference point that is located closest to that user. The RWGH algorithm can be basically viewed as a form of weighted least-squares algorithm. It is suitable for LOS, non-LOS (NLOS), and mixed LOS/NLOS channel conditions.

- TDOA: The idea of TDOA is to determine the relative position of the mobile transmitter by examining the difference in time at which the signal arrives at multiple measuring units, rather than the absolute arrival time of TOA. For each TDOA measurement, the transmitter must lie on a hyperboloid with a constant range difference between the two measuring units. A 2-D target location can be estimated from the two intersections of two or more TDOA measurements, as shown in Fig. 2.

Two hyperbolas are formed from TDOA measurements at three fixed measuring units (A, B, and C) to provide an intersection point, which locates the target P. The conventional methods for computing TDOA estimates are

Location Based Service of Ad Hoc Networks,

Fig. 2 Positioning based on TDOA measurements

to use correlation techniques. TDOA can be estimated from the cross correlation between the signals received at a pair of measuring units. The above two schemes have some drawbacks. For indoor environments, it is difficult to find a LOS channel between the transmitter and the receiver. Radio propagation in such environments would suffer from multipath effect. The time and angle of an arrival signal would be affected by the multipath effect; thus, the accuracy of estimated location could be decreased.

- **RSS-Based (or Signal Attenuation-Based) Method:** The power, or energy, of a signal traveling between two nodes is a signal parameter that contains information related to the distance (“range”) between those nodes. This parameter, commonly referred to as RSS, can be used together with a path loss and shadowing model to provide a distance estimate (Gezici 2008). Signal attenuation-based methods attempt to calculate the signal path loss due to propagation. Theoretical and empirical models are used to translate the difference between the transmitted signal strength and the received signal strength into a range estimate, as shown in Fig. 3.

Due to severe multipath fading and shadowing present in the indoor environment, path loss models do not always hold. The

Location Based Service of Ad Hoc Networks, Fig. 3 Positioning based on RSS, where LS1, LS2, and LS3 denote the measured path loss

parameters employed in these models are site-specific. The accuracy of this method can be improved by utilizing the premeasured RSS contours centered at the receiver (Van et al. 2017) or multiple measurements at several base stations. A fuzzy logic algorithm shown in Fallah and Pourahmadi (2018) is able to significantly improve the location accuracy using RSS measurement.

- **RTOF:** This method is to measure the time-of-flight of the signal traveling from the transmitter to the measuring unit and back, called the RTOF (see Fig. 1). For RTOF, a more moderate relative clock synchronization requirement replaces the above synchronization require-

ment in TOA. Its range measurement mechanism is the same as that of the TOA. The measuring unit is considered as a common radar. A target transponder responds to the interrogating radar signal, and the complete roundtrip propagation time is measured by the measuring units. However, it is still difficult for the measuring unit to know the exact delay/processing time caused by the responder in this case. In long-range or medium-range systems, this delay could be ignored if it is small, compared with the transmission time. However, for short-range systems, it cannot be ignored. An alternative approach is to use the concept of modulated reflection (Kim et al. 2016b), which is only suited for short-range systems. An algorithm to measure RTOF of wireless LAN packets is presented in D'Souza et al. (2016) with the result of a measurement error of a few meters. The positioning algorithms for TOA can be directly applicable for RTOF.

- **Received Signal Phase Method:** The received signal phase method uses the carrier phase (or phase difference) to estimate the range. This method is also called phase of arrival (POA) (Makki et al. 2015). Assuming that all transmitting stations emit pure sinusoidal signals that are of the same frequency, with zero phase offset, in order to determine the phases of signals received at a target point, the signal transmitted from each transmitter to the receiver needs a finite transit delay. In Fig. 4, the transmitter stations A up to D are placed at particular locations within an imaginary cubic building.

The receiver may measure phase differences between two signals transmitted by pairs of stations, and positioning systems are able to adopt the algorithms using TDOA measurement to locate the target.

Angulation Techniques (AOA Estimation)

In AOA, the location of the desired target can be found by the intersection of several pairs of angle direction lines, each formed by the circular radius from a base station or a beacon station to the

Location Based Service of Ad Hoc Networks, Fig. 4
Positioning based on signal phase

Location Based Service of Ad Hoc Networks, Fig. 5
Positioning based on AOA measurement

mobile target. As shown in Fig. 5, AOA methods may use at least two known reference points (1, 2) and two measured angles a_1 and a_2 to derive the 2-D location of the target P. Estimation of AOA, commonly referred to as direction finding (DF), can be accomplished either with directional antennae or with an array of antennae.

The advantages of AOA are that a position estimate may be determined with as few as three measuring units for 3-D positioning or two measuring units for 2-D positioning and that no time synchronization between measuring units is required. The disadvantages include relatively large and complex hardware requirement(s) and location estimate degradation as the mobile target moves farther from the measuring units. For accurate positioning, the angle measurements need to be accurate, but the high accuracy measurements in wireless networks may be limited by shadowing, by multipath reflections arriving from misleading directions, or by the directivity

of the measuring aperture. Some literatures also call AOA as direction of arrival (DOA). For more detailed discussions on AOA estimation algorithms and their properties, see Wu et al. (2017), Gui et al. (2017), and Gu and Ren (2015).

Scene Analysis

For triangulation methods, line-of-sight (LOS) scenario is always necessary, but in non-line-of-sight (NLOS) scenarios, scene analysis methods are more trustworthy.

RF-based scene analysis refers to the type of algorithms that first collect features (fingerprints) of a scene and then estimate the location of an object by matching online measurements with the closest *a priori* location fingerprints.

The term “location fingerprinting” covers a wide variety of methods for determining receiver position using databases from different sources, such as RSS, TOA, TDOA, multi-pass feature, and so on (Honkavirta et al. 2009). RSS-based location fingerprinting is commonly used in scene analysis. Location fingerprinting refers to techniques that match the fingerprint of some characteristic of a signal that is location dependent.

There are two stages for location fingerprinting: offline stage and online stage (or run-time stage). During the offline stage, a site survey is performed in an environment. The location coordinates/labels and respective signal strengths from nearby base stations/measuring units are collected. During the online stage, a location positioning technique uses the currently observed signal strengths and previously collected information to figure out an estimated location. There are at least five location fingerprinting-based positioning algorithms using pattern recognition technique so far: probabilistic methods, *k*-nearest-neighbor (kNN), neural networks, support vector machine (SVM), and smallest *M*-vertex polygon (SMP).

The techniques based on location fingerprinting utilize the diffraction, reflection, and scattering in the propagation indoor environments. The main challenge to fingerprinting-based technology is that the database is time-consuming, labor-intensive, and vulnerable to environmental

changes and the process requires certain pedigree on the surveyor that may deem the fingerprinting techniques impractical to be deployed over large areas (e.g., shopping malls, multistory offices/residences, etc.) (Hossain and Soh 2015). Researchers are trying to find some fast-rate fingerprint collection methods (Schmidt et al. 2018), such as crowdsourcing methods (Wang et al. 2016; Zou et al. 2013) and radio map simulation methods.

Proximity

Proximity algorithms provide symbolic relative location information. Usually, it relies upon a dense grid of antennas, each having a well-known position. When a mobile target is detected by a single antenna, it is considered to be collocated with it. When more than one antenna detects the mobile target, it is considered to be collocated with the one that receives the strongest signal. This method is relatively simple to implement. It can be implemented over different types of physical media. In particular, the systems using infrared radiation (IR) and radio frequency identification (RFID) are often based on this method. Another example is the Cell Identification (Cell-ID) or Cell of Origin (COO) method. Furthermore, many of the wireless sensor networks (WSN)-based positioning systems use proximity algorithms (Wang et al. 2010).

Positioning Strategies for Ad Hoc Sensor Networks Sun et al. (2005)

The unique properties of sensor networks cause them to require somewhat different positioning strategies than those used in cellular networks and WLANs. There are various possibilities for constructing a localization strategy that balances computation among sensor network nodes. These strategy designs include the distributed (every node should be able to estimate its own location), the localized (each node gathers information from other nodes in its immediate neighborhood), the asymptotic convergence design (computation stops when a certain degree of accuracy has

been achieved), the self-organizing scheme (node functioning does not depend on the global infrastructure), the robust design (the strategy can tolerate node failures and range errors), and the cost-effective and energy-efficient approach (this strategy requires little computation overhead).

Beacon-Based Versus Beacon-Free Strategies

Beacon-based strategies assume that a certain minimum number of nodes know their own positions through manual configuration or GPS. Individual nodes' location could then be determined by referring to a beacon's position. A detailed survey of various beacon-based localization strategies has been provided in Bulusu et al. (2004). All beacon-based positioning strategies, however, have their limitations because they need another positioning scheme to bootstrap the beacon node positions, and they cannot be easily employed in environments where other location systems are unavailable; thus, they are unsuitable for use indoors. It turns out, in practice, that a large number of beacon nodes are required to achieve an acceptable level of position error (Bulusu et al. 2004). In contrast, beacon-free strategies use local distance information to attempt to determine each node's relative coordinates without relying on beacons that are aware of their positions. Of course, any strategy that does not use beacon nodes can be easily converted to one that uses a small number of beacon nodes by adding a final step in the procedure, in which all node coordinates are transformed using three (in 2-D positioning) or four (in 3-D positioning) beacon nodes. For example, multidimensional scaling (MDS) has been investigated for use in solving the localization problem in sensor networks (Shang and Ruml 2004; Ji and Zha 2004). Without using beacons, all MDS-based localization strategies are able to produce maps that represent the relative positions of nodes. With three or more beacons, the absolute coordinates of all the nodes can be determined at the same time. Another fully distributed and beacon-free localization strategy, proposed in Priyantha et al. (2003), operates in two stages.

In the first stage, a heuristic is employed to create a well-spread, fold-free graph layout that resembles the desired layout. The second stage uses a mass-spring model analog. The optimized localization estimates analog can be found to be the minimum energy stage of the mass-spring model.

Incremental Versus Concurrent Strategies

Incremental strategies begin with only three or four core nodes being aware of their own coordinates. They then recursively add appropriate nodes to this set by calculating each node's coordinate using measured relative distances from nodes with previously known coordinates. These coordinate calculations are based on either simple triangle strategies or on local optimization schemes (Savarese et al. 2001). However, incremental strategies have limitations because they can propagate measurement error, resulting in poor overall network localization. Some incremental strategies can thus be applied in later stages of global optimization to reduce propagation error. Escaping from local minima and reaching global minima in the incremental stage continues to be a major challenge. In concurrent strategies, all nodes calculate and then refine their coordinates in parallel using local information. Some of these strategies use iterative optimization schemes that reduce the differences between measured distances and calculated distances based on current coordinate estimates (Priyantha et al. 2003). Concurrent optimization strategies have a better chance of avoiding local minima than incremental schemes. They can also avoid error propagation by continuously reducing global errors.

Range-Based Versus Range-Free Strategies

Many localization strategies rely on the distances between nodes: this is known as range-based localization. This type of distance estimation is usually implemented using signal strength decay, TOA, or TDOA for internode range estimation (Patwari et al. 2002). While range-based strategies require absolute point-to-point distance estimation (range) or angle estimation for positioning, range-free strategies

do not require this information. In addition to measuring range information, range-free localization strategies achieve position estimation by solving a convex optimization problem using a connectivity matrix of sensor nodes (Doherty et al. 2001). However, due to the unique ad hoc character of wireless sensor networks, many distributed solutions are more attractive than centralized designs. Sensors locate themselves at the centroid of the locations of beacons they can detect (Bulusu et al. 2000). Other strategies have assumed node-to-node communication can be used to convey the locations of all the beacons to all the sensors (Niculescu and Nath 2003; Nagpal et al. 2003). Using hop-count as an estimate of Euclidian distance (by computing the average distance between sensors in Niculescu and Nath (2003) or by analytically deriving it in Nagpal et al. 2003), a sensor can estimate its position via triangulation. Another novel “range-free” strategy determines whether a node lies inside or outside of the triangles formed by all possible sets of three beacons (called the APIT test) (He et al. 2003).

Single-Hop Versus Multiple-Hop Strategies

In multi-hop positioning systems, nodes typically do not receive beacon nodes’ signals directly. Given the influence of single-hop positioning systems such as cellular networks and WLANs, it is not surprising that the first multi-hop localization strategies tried to adapt single-hop technologies. TDOA, RSSI, and/or AOA information is collected, and the position of each node is then computed using triangulation (Niculescu and Nath 2003). A number of connectivity-based solutions have been proposed for multi-hop localization. One of the simplest and earliest is DV-hop (Niculescu and Nath 2003). In this system, each node determines its own position based on how many hops away it is from a beacon node. A method similar to APS was suggested in Nagpal et al. (2003). It first determines the hop distance (called gradient) to the beacons (called seeds) and, as a function of the average node density, calculates the actual average hop distance to a beacon.

Key Applications

Routing Optimize

For most of the self-organizing network technologies, position information is needed for relaying (Mauve et al. 2001; Liu et al. 2016). Routing problems of self-organizing network will be solved more convenient with the help of location information, because the distribution of the nodes is known and the power cost and the time delay of the multi-hop communication would be optimized (Li et al. 2009; Noguchi and Kobayashi 2017; Pham Thi Minh et al. 2015).

Node Placement

The working efficiency of ad hoc network is affected by the distribution of the nodes (Erdogan et al. 2003; Yan and Olariu 2009). To optimize this distribution of the nodes, the location information of the node is necessary. LBS provides this position information, and the nodes can be placed at right places or automatically move to the optimized place.

Target Detecting

Ad hoc net-based LBS can also be used for target detecting. The location of cooperative user can be calculated by the ad hoc net by ranging-based algorithms. And the position of uncooperative user can be detected by the RSS changes; this method can be used in security systems, landmine systems, or antisubmarine systems.

BAN Applications

Body area network (BAN) organizes the nearby gears of a user to provide a personalized service. Such a people-centered network needs the location of the user to organize the network, which can be provided by the LBS of ad hoc network.

IoT Applications

Internet of Things (IoT) is playing an important role in the society, i.e., express, library management, and find things. These applications all depend on the location information of things. Also, the network of these things are ad hoc networks, so ad hoc-based LBS becomes the first choice for the positioning services of them.

Definition

Long-term quality of protection (QoP) is envisioned to sustain personalized services with long-term privacy preservation.

Historical Background

Quality-of-protection (QoP) (Wang and Zhang 2015; Weber 2015) mechanisms have been exploited to thwart privacy breach in sharing user-generated content, including user's location information in location-based services (LBSs), and sensor data in participatory sensing (Wang et al. 2017). These mechanisms employ several QoP models that can be categorized into the following three classes (Wang and Zhang 2015).

Anonymization and generalization models. The crux of anonymization and generalization models is to replace a specific value of user's attributes (such as sensor data) with a coarser range to provide privacy protection (Zarrin et al. 2017). In LBS systems, the location coordinates of multiple users are transformed into the same geographical region to hide a user's specific location spot. In participatory sensing

systems, sensor data from multiple users can also be protected by releasing data of coarser granularity. The main advantage of anonymization and generalization models is that the generalized range truly includes the real value, and thus there is no falsified data. Whereas their limitations are also obvious: these techniques normally require a trusted third party to serve as the anonymizer. Moreover, these techniques work well under certain assumptions about adversaries' prior knowledge, while the users' privacy can be jeopardized in the presence of stronger adversaries, such as adversaries knowing the anonymization algorithm.

Randomization-based models. Randomization-based models include random perturbation and differential privacy techniques. Random perturbation transforms the original data by replacing a subset of the data points with randomly selected values, which can be generated by adding random noise to the original data or executing randomized algorithms. Differential privacy is achieved by injecting randomness into each user's data so that aggregated results are insensitive to the change of any single user's data. A major appealing feature of differential privacy is that it makes the worst case guarantee, that is, even if the adversaries know the data of all the individuals except the target individual, the adversaries are still uncertain about the data of the target individual. Though randomization-based models can defend a wider range of attacks than anonymization and generalization models, the loss of data quality and truthfulness caused by randomness is the main shortcoming.

Cryptographic techniques. End-to-end encryptions are widely adopted to secure the transmissions of users' reported data. These approaches mainly protect users' privacy from external adversaries (such as eavesdroppers), while internal adversaries (such as compromised or untrusted service providers) can decrypt the ciphertext to obtain users' data. Secure multiparty computation (SMC) allows multiple peers to jointly compute a function over their inputs without revealing inputs to each other.

However, SMC approaches are normally limited to specific computations and incur substantial communication or computation overhead.

Many studies leverage the above techniques to enable privacy preservation in LBSs or participatory sensing applications. Most of them are designed for protecting data privacy in single-shot scenarios, or focus on static attacks, while the user's two-level sensitivities and the context-aware adversaries cannot be covered by these techniques. In particular, the framework should be carefully designed to guarantee user's QoP requirements (context sensitivity and data sensitivity) against context-aware adversaries (passive and active adversaries) and different attacking strategies (static and adaptive attacks). To this end, QoP frameworks for long-term services are exploited to satisfy user's QoP requirements under different types of attacks.

The long-term QoP mechanisms are designed for long-term services where a user encounters a series of contexts and transits between various contexts (Wishart et al. 2015). The gamut of contexts is a set of interrelated user states and environmental conditions that are logically and temporally correlated (Gotz et al. 2012). The mobile user usually goes to a coffee shop after leaving home – this temporal correlation is the user's habit that can be learned from the user's historical data. The mobile user walks on the street after having coffee in the coffee shop – in this case, the context “walking” has logical relation with the context “in coffee shop” as a user needs to walk out of the coffee shop after having coffee.

Key Applications

Long-term QoP is designed to offer protection for long-term services. A range of sensors equipped on smart devices have been effectively used to infer user's contexts including location from GPS or wireless signals (Wi-Fi or cellular signals), mobility modes from accelerometer, and social activities from a combination of multiple sensors. Consequently, a large bundle of person-

alized services are emerging by utilizing user-generated sensor data. Smart devices carried by a mobile user continuously acquire readings from equipped sensors and periodically upload the data to corresponding service providers via the user's smartphone. After receiving the user-generated sensor data, service providers perform a series of actions to process the data, including context acquisition, preprocessing, storing, and reasoning within the application boundaries. The target of these actions is to “understand” the current state of the user and environmental conditions, based on which service providers deliver personalized services to the user. These personalized services can be categorized into:

Passive services. This type of services passively tracks the user's activities or conditions for offline analysis. Examples are healthcare monitoring and activity tracking applications such as Apple Healthbook and FitBit.

Active services. This type of services recognizes the user's contexts in real time and autonomously takes actions based on the current context. For example, an iOS application named AutoSilent automatically mutes the phone when the user is in a meeting.

Synonyms

Low-latency millimeter-wave networks

Definitions

The overall latency in communication networks is defined as the time span of completing the transmission from the source to the destination, which generally comprises: propagation delay (sending one bit to receiver via the physical medium), transmission delay (pushing the packet into the communication medium in use), processing delay (analyzing a packet header, making a routing decision, and processing signals), and queuing delay (waiting in the queue for transmission).

Historical Background

Low latency is a critical feature in future wireless communications, i.e., the fifth-generation (5G) mobile networks, which can significantly improve the quality of service (QoS). It is

reported in Andrews et al. (2014) and Osseiran et al. (2014) that the anticipated 5G systems should enable the latency as low as a few milliseconds, and this requirement is more stringent than those in the existing 3G/4G systems, thereby posing huge challenges to related system development and implementation.

Fortunately, millimeter-wave (mm-wave) technologies as promising candidates in future mobile networks enable low-latency communications. The mm-wave radios in 5G networks usually refer to the electromagnetic waves with frequency among the spectra from 24 to 300 GHz. In mm-wave bands, the abundant spectral resources and dense antenna arrays (thanks to the short wavelength) can provide evidently higher data rates than those in sub-6 GHz bands, thereby paving a road for achieving low-latency communications. The features of mm-wave communications and the progress of mm-wave technologies are comprehensively summarized by Rappaport et al. (2013), Rangan et al. (2014), Xiao et al. (2017).

Driven by the ever-increasing demands on latency-sensitive applications and the huge benefits of mm-wave technologies, low-latency communications with mm-wave as a hot topic have attracted extensive attention. Numerous recent efforts have been devoted to the research on this topic, yielding many excellent achievements, e.g., Levanen et al. (2014), Filippou et al. (2017), Nielsen et al. (2018).

Related Works

In what follows, an overview that briefly summarizes several typical works in recent years regarding low-latency mm-wave communications is provided.

From the perspective of the transport-layer protocol, Polese et al. (2017) provided an overview regarding the impacts of mm-wave communications on the performance of the transmission control protocol (TCP), in terms of the end-to-end latency and reliability. Also, motivated by multiconnectivity in mm-wave

communications, the authors investigated the potential of the recent multipath TCP (MP-TCP) option in improving the network performance. It was revealed by Polese et al. (2017) that an optimized interaction between the transport-layer protocol and mm-wave network plays an important role in enabling low-latency 5G communications.

Using stochastic network calculus based on moment generating function (MGF), the probabilistic end-to-end latency was investigated by Yang et al. (2018a) for mm-wave multihop networks with full-duplex buffer-aided relays. Specifically, with lognormally distributed shadowing incorporated in mm-wave channels, upper bounds for the probabilistic end-to-end latency were developed to keep track of the latency performance, and a delay-optimum power allocation scheme subject to a sum-power constraint was also developed in the presence of self-interference. Yang et al. (2018a) provided an analytic method that can assess the probabilistic end-to-end latency of multihop networks in a straightforward manner, and also showed important clues for optimizing the power allocations in the presence of self-interference and constrained sum-power budget.

For the two distinct transmission schemes, namely, network densification (refer to serial transmission) and traffic dispersion (refer to parallel transmission), the low-latency capabilities were investigated by Yang et al. (2017) for mm-wave networks with buffers. In addition to the MGF-based network calculus method, effective capacity was adopted to characterize the service capability, which is related to the maximum traffic density that can be afforded by system without causing infinite latency. A hybrid scheme based on a flexible combination of network densification and traffic dispersion was also investigated. Given a fixed source-destination distance, it was shown by Yang et al. (2017) that the different low-latency capabilities of the three schemes heavily depend on the sum-power budget and the arrival rate.

Focusing on the massive multiple-input multiple-output (MIMO) network with mm-wave, Vu et al. (2017) investigated a trade-

off between capacity improvement and latency reduction. Specifically, the authors formulated a network utility maximization problem associated with probabilistic latency and reliability constraints and resorted to the Lyapunov method that adapts to channel variations and queue dynamics for seeking a utility-optimum solution. It was shown that the optimization problem can be decomposed into a dynamic latency control and rate allocation. Numerical results demonstrated that the approach proposed by Vu et al. (2017) exhibits promising gains in latency reduction.

Hashemi et al. (2018) proposed an architecture that integrates the sub-6 GHz and mm-wave technologies, exploiting the spatial correlations between interfaces for beamforming and data transfer, more precisely, the sub-6 GHz interface as a secondary option to assist the mm-wave interface. In addition, the authors formulated a scheduling problem regarding assigning the arrival traffic between the sub-6 GHz and mm-wave interfaces, where the two interfaces were treated with dedicated queues, as two individuals aiming to maximize the mm-wave throughput subject to a bounded delay. It was shown by Hashemi et al. (2018) that the optimal scheduling policy is threshold-based, which can be easily applied in spite of fast-varying mm-wave channels.

In the heterogeneous network (HetNet) with mm-wave, the latency performance of traffic allocation and cooperative networking was investigated by Yang et al. (2018b). Considering a simple HetNet that comprises one macro-cell evolved NodeB (MeNB), two small-cell evolved NodeBs (SeNBs), and one user equipment (UE), the authors resorted to the optimal traffic allocations and cooperation among MeNB and SeNBs, aiming to minimize the end-to-end latency in a downlink transmission. Yang et al. (2018b) revealed that traffic allocation and cooperative networking are capable of significantly reducing the latency in mm-wave HetNets, while the complexity will be a huge concern as the network size scales up.

In addition to the above studies towards specific technical problems, there are several

surveying works summarizing the state-of-the-art research regarding low-latency communications in 5G from various aspects. Recently, a survey on the emerging technologies for low latency towards 5G was presented by Parvez et al. (2017), where the potential solutions in the three domains, i.e., radio access network (RAN), core network, and caching, were extensively investigated. Another comprehensive survey was presented by Ford et al. (2017), which summarized some challenges and potential solutions for providing reliable and low-latency services in mm-wave systems. The state-of-the-art research was reviewed from the following three aspects in high-layer designs: core network architecture, medium access control (MAC), and congestion control. It was concluded by Ford et al. (2017) that, to achieve low latency in mm-wave communications, it is crucial to make data and services physically closer to the end user and to enable flexible and scalable network deployment and functionality management. In addition, flexible MAC layer with low-latency scheduling and fast adaptive congestion control against fast-varying mm-wave channels are important.

Key Applications

Low latency plays an extremely important role in a broad class of use cases, especially for those latency-sensitive and/or mission-critical applications, including, e.g., virtual reality (VR), augmented reality (AR), intelligent transportation systems (ITS), tactile Internet, vehicle-to-vehicle (V2V), industrial control and automation, remote healthcare applications, robotics, and telepresence.

MAC in Cognitive Radio Networks

[Media access control protocol for cognitive radio networks](#)

Definitions

In cognitive radio networks, the media access control (MAC) protocols need to determine the availability of spectrum resource through spectrum sensing and coordinate with the other secondary users (SUs) for spectrum access, so that the spectrum resource is efficiently utilized without harmful interference to the primary users (PUs).

Historical Background

Cognitive radio has been first proposed in Mitola and Maguire (1999) and Mitola (2000) as a way to promote the efficient use of the spectrum by exploiting spectrum opportunities. SUs with cognitive radios are able to exploit information about the wireless environment and adapt their

transmission parameters to access available channels while avoiding harmful interference to PUs (Haykin 2005).

In general, there are three transmission schemes for cognitive radios: underlay, overlay, and interweave (Goldsmith et al. 2009). In underlay scheme, SUs are allowed to transmit signal as long as the generated interference stays below a certain threshold. In 2003 the FCC defined the interference temperature as a way to measure and limit the interference at PUs. However, this model has been abandoned by the FCC in 2007 due to the implementation issues. In overlay scheme, SUs exploit the knowledge of PUs' messages to either limit the interference. In interweave scheme, SUs can only transmit in spectrum holes; whenever a SU detects PUs, the SU vacates its channel to avoid harmful interference to PUs.

In order to realize the functions of cognitive radios, MAC should possess the ability of channel sensing, resource allocation, spectrum sharing, and spectrum mobility (Akyildiz et al. 2006). Channel sensing is the ability of a cognitive radio to collect information about spectrum usage. Resource allocation is employed to opportunistically assign available channels to SUs according to QoS requirements. Spectrum sharing deals with contentions between heterogeneous PUs and SUs in order to avoid harmful interference. Spectrum mobility allows a SU to vacate its channel, when a PU is detected, and to access an idle band where it can reestablish the communication link. The research works

of cognitive radio MAC mainly focus on these aspects, which is reviewed in several surveys (Krishna and Amitabha 2009; De Domenico et al. 2012; Cormio and Chowdhury 2012). Apart from the close coupling of physical layer and MAC layer, there also exist interactions between the network and transport layers with MAC layer, such as joint spectrum and route decisions, congestion-free end-to-end reliability, spectrum and node mobility, etc. (Akyildiz et al. 2009).

On the standardization side of cognitive radio, IEEE 802.22 represents the major effort, which was started in 2004 and finalized in 2011 (Cordeiro et al. 2005). 802.22 is designed for wireless regional area networks (WRANs) which takes advantage of the favorable transmission characteristics of the VHF and UHF TV bands to provide broadband wireless access over a large area up to 100 km from the transmitter. 802.22 MAC uses time division multiplexing, with structures of superframe and frame, where a superframe is composed of multiple MAC frames preceded by the frame preamble. In addition to 802.22, the IEEE has standardized another white space cognitive radio standard, 802.11af, which was approved in 2014 (Flores et al. 2013). 802.11af is a wireless LAN standard designed for ranges up to 1 km. 802.11af uses carrier sense multiple access with collision Avoidance (CSMA/CA)-based MAC protocol.

Foundations

Due to the unique requirement of protection for PUs, the design of cognitive radio MAC protocols is different from MAC protocols of most of the other wireless systems. The cognitive radio MACs are based on the closed coupling with the physical layer and the hardware support on the radio device.

Spectrum sensing is one of the key enabling functions in cognitive radio networks that is used to explore vacant spectrum opportunities and to avoid interference with the PUs. While the physical layer of spectrum sensing is responsible for the signal processing work, the MAC layer

is more involved in the higher-level functions of spectrum sensing coordination. For example, MAC layer needs to optimize sensing and transmission durations, the order in which channels are sensed, and the number of channels to be sensed before transmission (Kim and Shin 2008; Lee and Akyildiz 2008; Jia et al. 2008). Furthermore, the reliability of spectrum sensing can be improved if SUs share their sensing results with neighbors due to multiuser spatial diversity, which is called cooperative spectrum sensing. However, the improvement of spectrum sensing comes at the cost of increased latency and communication overhead, where the MAC layer tries to coordinate multiple SUs and reduce the cost.

Since cognitive radio networks usually use multiple channels, control channel establishment needs to be carefully considered, especially for distributed networks. Some MAC designs assume there exists a global control channel available for all SUs, which simplifies the implementation (Ma et al. 2005). When a global control channel is not available or reliable, local control channels can be used, since it is possible that neighboring SUs may share some commonly available channels (Zhao et al. 2005; Chen et al. 2005). Besides, some designs do not use a dedicated control channel at all, which is based on channel hopping. The coordination of channel hopping in such context is usually referred to as rendezvous (Lin et al. 2011; Bian et al. 2011).

Spectrum allocation is an important function of the MAC protocol in cognitive radio networks. Since the spectrum availability and transmission requirement at SUs could be different, SUs have to share their spectrum availability information with neighbors and conduct efficient spectrum allocation to maximize certain utility. MAC protocols exploit advanced optimization algorithms to realize intelligent, fair, and efficient allocation of the available spectrum. Each SU adapts its transmission parameters to changes of the wireless environment, in order to efficiently exploit the available resource. Considering the high complexity of centralized optimization, decentralized approaches in which each SUs acts based on partial knowledge of network status have been

proposed based on graph coloring theory (Zheng and Peng 2005), game theory (Wang et al. 2010), stochastic theory (Zhao et al. 2007), etc.

Spectrum access enables multiple SUs to share the spectrum resource by determining who will access the channel or when a user accesses the channel. Contentions between SUs can be avoided through coordinated access both in centralized and distributed architectures. When coordination is absent, a random approach could be exploited to contend for access to available channels (Zhao et al. 2007). Otherwise, SUs may exchange signalling messages in order to reserve the access to a data channel (Su and Zhang 2008). The control handshaking mechanism, however, does not completely solve the hidden terminal problem; hence the busy tone scheme is often exploited to prevent hidden nodes (Ma et al. 2005).

When a PU is detected, to realize seamless transmission, a cognitive radio vacates its channel and reconstructs a transmission link on a different channel. The procedure that permits this transition from a channel to another with minimum performance degradation is called handoff. Spectrum mobility in MAC layer is to reduce delay and loss during spectrum handoff. In general, there are two different strategies for spectrum mobility: proactive spectrum handoff and reactive spectrum handoff (Akyildiz et al. 2009). In proactive spectrum handoff, SUs predict future activity in the current link and determine a new spectrum while maintaining the current transmission and then perform spectrum switching before the link failure happens. For proactive spectrum handoff, the spectrum switching is faster but requires complex algorithms. On the other hand, in reactive spectrum handoff, SUs perform spectrum switching after detecting link failure due to spectrum mobility. This method requires immediate spectrum switching without any preparation time, resulting in significant quality degradation in ongoing transmissions. It is also possible to design a hybrid spectrum handoff strategy, which combines proactive strategy and reactive strategy by applying proactive spectrum sensing and reactive handoff action (Christian et al. 2012).

Key Applications

MAC protocol is a fundamental component for cognitive radio networks.

Definition

In usual ways of programming, a program is built by building instructions in order to reach desired outputs from inputs. However, in machine learning (ML), that process is flipped. The inputs and desired set of outputs are given, and the program should learn what instructions or policy should be followed. ML is concerned with algorithms that observe data, learn from it, grow up, and make more intelligent decisions. Based on the way that machines accumulate knowledge and become able to function as needed, ML can be classified into supervised, semi-supervised, unsupervised, and reinforcement learning.

Historical Background

Internet of Things (IoT) systems are built on thousands of wireless sensor networks (WSNs). WSNs suffer from various limitations such as finite energy, hardware inaccessibility, uncontrolled environment, uncontrolled topology, limited computational power and storage capability,

and heterogeneity in systems. Recent developments of WSN technologies have targeted energy efficiency, lifetime, coverage, connectivity, traffic balancing, spectrum management, fault tolerance, latency, reliability, and security, among others. These targets can be improved by considering controlled deployment and mobility, routing, scheduling, power and rate control, clustering, data aggregation, in-network processing, and traffic control. One of the most important aspects of WSNs and IoT systems is traffic control through traffic reduction. Traffic reduction is done by reducing the amount of data or packets that need to be transferred across WSNs and various IoT layers. This improves IoT systems in terms of energy and spectrum, which are the main resources, and increases lifetime. Traffic control can be implemented in IoT systems using machine learning (ML) algorithms.

ML algorithms observe data, learn from it, grow up, and make intelligent decisions. Through training, machines build policies to perform complex tasks that mimic intelligent human behavior. ML tools have the potential to provide lower-complexity alternatives for sophisticated algorithms that consume time and resources. Also, ML makes it easy to deduce hidden correlations, understand context, and make predictions from the collected data. It also provides autonomous and intelligent decision making schemes with minimal human intervention. The importance of applying ML approaches in IoT systems and WSNs is mainly due to the dynamicity and uncontrollability of the surrounding environment (Alsheikh et al. 2014). Deep neural networks (DNNs) and long short-term memory networks (LSTMs) are supervised ML techniques. They are used to improve WSNs in various applications. In this chapter, both will be studied and proposed as a key application for traffic reduction in IoT systems.

The remainder of this chapter is organized as follows. First, mathematical computational graphs of DNNs and LSTMs are used to illustrate how they work. After that, their applications to WSNs and IoT systems are studied. Finally, both techniques are used to improve traffic reduction through IoT systems.

Foundations

Deep Neural Networks (DNNs)

Deep learning is a machine learning technique where learning is done through multiple levels of representations (Chen and Lin 2014). Deep neural networks (DNNs) mimic how humans' brains work in the sense that they are composed of many abstraction layers. Each layer draws conclusions based on the previous layer outputs. They are widely used in feature extraction, modeling complex relationships between inputs and outputs, and context understanding.

DNNs are represented in computational graphs as shown in Fig. 1. The illustrated DNN consists of L layers. The l th layer takes an $n^{[l-1]} \times 1$ vector $\mathbf{a}^{[l-1]}$ and outputs another $n^{[l]} \times 1$ vector $\mathbf{a}^{[l]}$ that goes as an input to the next layer, where $n^{[l]}$ is the number of neurons at the l th layer. The output of each layer is computed from its input. In the figure, $\mathbf{w}^{[l]}$ is the l th layer $n^{[l]} \times n^{[l-1]}$ weight matrix, $\mathbf{b}^{[l]}$ is its $n^{[l]} \times 1$ bias, and $g(\cdot)$ is an element-wise activation function. The activation function $g(\cdot)$ can be Sigmoid, tanh, rectified linear unit (ReLU) functions, among others.

As a supervised learning approach, the DNN is trained using a labeled data set. The goal of building a DNN is to map a new input $\mathbf{X}$ to an output $\mathbf{Y}$ based on the labeled inputs. During this phase, a cost function $J(\mathbf{w}^{[1]}, \mathbf{b}^{[1]}, \mathbf{w}^{[2]}, \mathbf{b}^{[2]}, \dots)$ is defined in terms of outputs $\mathbf{Y}$ and labels $\mathbf{d}$ as shown in Fig. 1. For example, the cost can be defined as the mean square error (MSE).

The DNN output $\mathbf{Y}$ is computed using the computational graph in Fig. 1. This process is called forward propagation. During training, the gradients $d\mathbf{w}^{[l]} = \partial J / \partial \mathbf{w}^{[l]}$ and $d\mathbf{b}^{[l]} = \partial J / \partial \mathbf{b}^{[l]}$ at every layer are computed. After that, they are used to update (tune) the weights and biases in a process that is called backward propagation. Weights and biases updates are done using various iterative optimization algorithms such as gradient descent (GD) or Adam optimizer. In GD algorithm, the updates are done using $\mathbf{w}^{[l]} := \mathbf{w}^{[l]} - \alpha d\mathbf{w}^{[l]}$ and $\mathbf{b}^{[l]} := \mathbf{b}^{[l]} - \alpha d\mathbf{b}^{[l]}$, where $:=$ denotes the update operator and α represents the learning rate. Gradients and updates are done

Machine Learning in Wireless Sensor Networks for the Internet of Things, Fig. 1 DNNs computational graph architecture

numerically using frameworks such as TensorFlow (Rampasek and Goldenberg 2016). It is emphasized that TensorFlow is optimized to calculate gradients because it is based on computational graphs where the chain rule is used to compute derivatives.

Long Short-Term Memory Networks (LSTMs)

Long Short-Term Memory networks (LSTMs) represent a special kind of recurrent neural networks (RNNs). LSTMs are good in handling sequence dependencies where the inputs are represented in terms of time, such as in prediction and language processing problems. An LSTM network is composed of a single LSTM cell that has a feedback connection from its output to its input. The structure of an LSTM cell is shown in Fig. 2. It is shown that at any time instance t , the LSTM cell input is composed of the current input (x_t) and the outputs from the previous time instance (h_{t-1} and c_{t-1}). LSTMs can be mathematically considered as multiple cells that are connected in cascade as shown in Fig. 3. However, it differs from DNNs in the sense that all LSTM cells in the cascade connection use the same weights and biases.

The LSTM cell contains four NNs that are connected to form three gates: forget (f), input (i), and output (o) gates as shown in Fig. 2. Each NN comprises one neurons layer with H number of neurons. The weights and biases of these NNs are denoted by w_f , b_f , w_i , b_i , w_c , b_c , w_o , and b_o . In general, during the training phase, these variables are updated so that the LSTM performs as required. Each LSTM cell has a state c_t and an output h_t at time instance t . Both cell state and output are fed to the LSTM in the next time

instance $t + 1$. The new cell state and output are calculated from previous state, previous output, and current input using the computational graph in Fig. 2. The cost function and variable tuning (backward propagation) can be done similar to what has been illustrated in DNNs.

Key Applications

Applications of DNNs and LSTMs in IoT Systems

DNNs are used to tackle many applications in IoT (Chen et al. 2017). For instance, DNNs are powerful for big data analytics (Mohammadi et al. 2018). Therefore, they are used to extract patterns and conclusions from data gathered by IoT devices. For example, DNNs can be used in context awareness applications such as human activity recognition in wearable WSNs. Moreover, DNNs are used to make predictions using simple information as input. Also, they can be used for classification problems which can be applied to many aspects in WSNs and IoT. Furthermore, DNNs have many applications in automation and building self-organizing networks which are the essence of IoT systems. The recent literature has proposed many applications of DNNs in applications related to IoT systems. In Bande and Shete (2017), DNNs are used for flood management in IoT systems to predict floods. The proposed framework has been applied to data collected from Chennai region. In Kumar and Jain (2018), localization in IoT scenarios has been implemented using DNNs. Localization is critical to many application where nodes location should be monitored, while GPS devices are not feasible to be used. DNNs are

Machine Learning in Wireless Sensor Networks for the Internet of Things, Fig. 2 Computational graph of a single LSTM cell

Machine Learning in Wireless Sensor Networks for the Internet of Things, Fig. 3 Prediction architecture using LSTMs

used to improve tracking in WSNs as well, as discussed in Luo et al. (2016).

Due to their gated and memory architecture, LSTMs are suitable for extracting patterns where the input data spans over long sequences. Therefore, LSTMs are suitable for prediction and time-series analytics (Jansen et al. 2018). They can be also used to extract features from long sequences (Liu et al. 2016). Moreover, LSTMs have some implementations for filling missing data points in data sets (Lipton et al. 2016). In literature, many LSTM applications can be found in WSNs and IoT research. For instance, LSTMs are commonly used architectures for short-term traffic flow prediction as illustrated in Ali and Mahmood (2018). In Aydin and Guldamlasioglu (2017), LSTMs

are used for maintenance systems in predicting the condition of components in factories and autonomous IoT systems.

In order to illustrate the applicability of using DNNs and LSTMs in IoT systems, they are applied to traffic reduction problem. Next, the dual prediction scheme and its performance when applying DNNs and LSTMs will be studied.

Traffic Reduction in IoT Systems Using Dual Prediction

Most of the collected data is usually redundant and can be mined from other observations due to the existence of a temporal correlation. Preventing the unnecessary transmissions in a WSN has a significant impact on reducing

Machine Learning in Wireless Sensor Networks for the Internet of Things, Fig. 4 DP scheme at Node 30 using OSSLMS, DNNs, and LSTMs

energy consumption and bandwidth usage. One approach to reduce data transmission between any two endpoints is to use dual prediction (DP) (Wu et al. 2016). The endpoints can be a node-to-node, node-to-gateway, or node-to-cloud. The DP scheme is based on data prediction algorithms that can be implemented using DNNs or LSTMs.

The two ends of the DP scheme are a source of data (S) and a destination (D). Let us assume

that a data buffer of size N is used to hold the last N observations at S and D. The DP scheme at S can be explained as follows. At the n th time slot, the data buffer is represented as $X_n = [x_{n-1}, x_{n-2}, \dots, x_{n-N}]$ where x_{n-i} represents the data point in the buffer at the $(n-i)$ th time slot. Initially, for the first N time slots, collected observations are transmitted from S to D and placed in the data buffer X_n . After that, when observation O_n is made at time slot n , the

Machine Learning in Wireless Sensor Networks for the Internet of Things, Fig. 5 DP scheme performance while using different accuracy levels

information in X_n is used to predict the observed value. The implemented prediction algorithms take X_n as input and generates a prediction P_n at time slot n . If the predicted value P_n was not close enough to the observed value O_n ($|P_n - O_n| > e_{\max}$ where $e_{\max}$ is the maximum acceptable prediction error), then the data buffer will be updated as $X_{n+1} = [O_n, x_{n-1}, \dots, x_{n-N+1}]$. Also, O_n is transmitted to D, and the value O_n is used to update the prediction model variables. However, if the predicted value P_n was close enough to the observed value O_n ($|P_n - O_n| \leq e_{\max}$), then $X_{n+1} = [P_n, x_{n-1}, \dots, x_{n-N+1}]$ and no transmission occurs because this observation can be predicted accurately. Also, the value P_n is used to update the prediction model. Following this scheme at S eliminates the need for transmitting the observations that can be accurately predicted at D.

The DP scheme at D is implemented as follows. During the first N time slots, the received observations are just saved at buffer X_n . After that, whenever an observation O_n is received, it is saved in the buffer as the newest data point and used to update the prediction model. However, if no observation is received at time slot n , then it means that this point can be predicted accurately; therefore, the prediction model is used to generate the corresponding observation. After that, the predicted point is used to update the prediction model and is added to the data buffer. It should be noted that the transmitting and receiving ends use the same prediction model. Also, they perform

the same model updates; therefore, both models are synchronized.

To evaluate our proposed models, the results are compared with optimal step-size least mean square (OSSLMS) algorithm that is discussed in Wu et al. (2016). The simulation has been performed on sample data collected by the Intel Berkeley research lab during a 1-month period that includes temperature, humidity, and light intensity. It is assumed that one node in Intel's WSN tries to send temperature readings periodically to another end which can be a cluster head, edge node, or cloud. It is assumed to be the cloud here. In any case, the DP scheme has the same performance.

The following parameters have been set for evaluation: the acceptable error threshold is $e_{\max} = 0.5^\circ\text{C}$ and the data buffer size $N = 10$. Figure 4 shows the performance of the DP scheme when using OSSLMS, DNNs, and LSTMs for predictions. It shows how the observed (at Node 30), predicted (at Node 30 and the cloud), and perceived (at the cloud) data changes over 100 time epochs. It can be seen that DP scheme's perceived data points (red) are equal to the predicted values (green) when the prediction is accurate and equal to the observed values (blue) when the prediction is not. Also, the error between the observed values (at Node 30) and the perceived ones (at the cloud) does not exceed $e_{\max}$ at any point. Figure 5 shows the percentage of traffic reduction and the MSE while varying the acceptable

error value $e_{\max}$. It shows how the proposed DNN and LSTM algorithms outperform recent literature algorithms such as OSSLMS. While all have the same MSE performance, DNN and LSTM outperform OSSLMS in terms of traffic reduction.

Definitions

Investigating machine learning aided cooperative resource allocation and network association mechanisms for wireless networks.

Introduction

Wireless network association has received substantial attention both in the academic

and industrial communities. One of their driving forces is that of efficiently providing unprecedented data rates for supporting radical new applications (Jiang et al. 2017). Specifically, a range of network association schemes are expected to learn the diverse and colorful characteristics of both the users' ambience and the human behaviors, in order to autonomously determine the optimal system configurations for the sake of conserving energy as well as maximizing network capacity. Moreover, smart mobile terminals have to rely on sophisticated learning and decision-making. Machine learning, as one of the most powerful artificial intelligence tools, constitutes a promising solution for wireless network association (Alsheikh et al. 2014).

Machine learning has found wide-ranging applications in image/audio processing, finance and economics, social behavior analysis, etc. Explicitly, a machine learns the execution of a particular task **T**, with the goal of maintaining a specific performance metric **P**, based on a particular experience **E**, where the system aims for reliably improving its performance **P** while executing task **T**, again by exploiting its experience **E**. Machine learning algorithms can be simply categorized as *supervised learning* and *unsupervised learning*, where the adjectives "supervised/unsupervised" indicate whether there are labeled samples in the database. Later, *reinforcement learning* emerged as a new category, which was inspired by behavioral psychology. It is concerned with an agent's certain form of reward/utility, who is connected to its environment via perception and action. Relying on a cascade of multiple layers of nonlinear processing units for feature extraction and transformation, *deep learning* was applied to network association for the sake of its expressive capacity and convenient optimization capability compared with conventional machine learning algorithms.

In wireless networks, machine learning can be widely used in modeling various technical problems of large-scale MIMOs, device-to-device (D2D) networks, heterogeneous networks (Het-Nets), cognitive radio, etc. (Clancy et al. 2007).

In this entry, we will introduce the basic concept of machine learning algorithms and their corresponding applications in network association according to the category of supervised, unsupervised, reinforcement learning, and deep learning.

Supervised Learning in Network Association

Models

The *k*-nearest neighbor (KNN) and *support vector machines* (SVM) are conceived for classification of points/objects relying on a D-dimensional vector **x** of input variables. In KNN, an object is classified into a specific category by a majority vote of the object's neighbors, with the object being assigned to the class that is most common among its *k*-nearest neighbors. By contrast, the SVM relies on a nonlinear mapping, which transforms the original training data into a higher dimension where it becomes separable and then it searches for the optimal linear separating hyperplane that is capable of separating one class from another in this higher dimension.

The philosophy of *Bayesian learning* is to compute the a posteriori probability distribution of the target variables conditioned on its input signals and on all of the training instances. Some simple examples of generative models that may be learned with the aid of Bayesian techniques include, but are not limited to, the *Gaussian mixture model* (GM), *expectation maximization* (EM), and *hidden Markov models* (HMM). Specifically, GM is a model where each data point belongs to one of several clusters or groups, and the data points within each cluster are Gaussian distributed. EM is a generalization of maximum likelihood estimation, which iteratively finds the most likely solutions or parameters. It is characterized by two steps, i.e., the "E" step and the "M" step. HMM is a tool designed for representing probability distributions of sequences of observations. It can be considered a generalization of a mixture-based model, where the hidden variables, which control the specific mixture of the component to be selected for each observation, are related to

each other through a Markov process, rather than being independent of each other.

Applications

In the following, some applications of supervised learning aided network association algorithms are elaborated, which are also summarized in Table 1. KNN algorithms are beneficial for traffic prediction, for anomaly detection, as well as for modulation classification. Specifically, in order to capture the dynamic characteristics of radio resource demands, a weighted KNN model was proposed based on a large-scale historical data set from cellular operator networks, which was used to explore both temporal and spatial characteristics of radio resource margins to enhance the load balance (Feng et al. 2017). Moreover, the authors of Onireti et al. (2016) proposed a KNN-based anomaly detecting algorithms for improving cell outage detection accuracy. In Aslam et al. (2012), genetic programming and KNN were combined in order to improve the modulation classification accuracy, which provided a reliable modulation classification scheme for the secondary users (SU) in cognitive radio networks.

Furthermore, the SVM-aided learning models can be used for estimating radio parameters, for predicting mobile terminal’s usage pattern, and for guiding channel selection. For example, in order to generalize the SVM function for employment in data classification problems, its hierarchical version referred to as H-SVM was proposed in Feng and Chang (2012), where each hierarchical level consisted of

a finite number of SVM classifiers. This regime was used for the estimation of the Gaussian channel’s noise level in a MIMO-aided wireless network. By exploiting the training data, the H-SVM model was trained for the estimation of the channel noise statistics. SVM can also be used for learning the mobile terminal’s specific usage pattern in diverse spatiotemporal and device contexts, as discussed in Donohoo et al. (2014). This may then be exploited for prediction of the configuration to be used in the location-specific interface for HetNets constituted by diverse cells. In Thilina et al. (2016), the common control channel for SUs during a given frame was selected by employing an SVM-based learning technique for a cognitive radio network, which was capable of implicitly learning the surrounding environment cooperatively in an online fashion.

The Bayesian learning model may be readily invoked for spectral characteristic learning and estimation. The authors of Wen et al. (2015) estimated both the channel parameters of the desired links in a target cell and those of the interfering links of the adjacent cells, relying on the sparse Bayesian learning techniques, where the channel component was first modeled by a GM, and then estimated with the aid of the EM algorithm. In Choi and Hossain (2013), a cooperative wideband spectrum sensing scheme based on the EM algorithm was proposed for the detection of a primary user (PU) supported by a multi-antenna assisted cognitive radio net-

work. Furthermore, in Assra et al. (2016), the authors constructed a HMM relying on a two-state hidden Markov process, where the PUs are present or absent, and a two-state observation space, indicating whether the PUs are present or absent. Furthermore, the EM algorithm was invoked for finding the true channel parameters, such as the sojourn time of the available channels, the inactive states of the PUs, as well as the PUs' signal strength.

Unsupervised Learning in Network Association

Models

K-means clustering aims for partitioning n observations into k clusters, where each observation belongs to the closest cluster. It defines the centroid of a cluster as the center of gravity, i.e., the mean value of the points within the cluster. The clustering algorithm proceeds in an iterative manner, where an object is assigned to the specific cluster whose centroid is nearest to the object based on the Euclidean distance, and then the in-cluster differences are minimized by iteratively updating the cluster centroid, until convergence is achieved.

Principal component analysis (PCA) transforms a set of potentially correlated variables into a set of uncorrelated variables referred to as the principal components, where the number of principal components is less than or equal to the number of original variables. Basically, the first principal component has the largest possible variance, and each succeeding component in turn has the highest variance possible under the constraint that it is orthogonal to the preceding components. The principal components are orthogonal, because they are the eigenvectors of the covariance matrix, which is symmetric. By contrast, *independent component analysis* (ICA) is a statistical technique conceived for revealing hidden factors that underlie sets of random variables, measurements, or signals. In the model, the data variables are assumed to be linear mixtures of some unknown latent variables, and the mixing system is also unknown. The latent variables

are assumed to be non-Gaussian and mutually independent, and they are referred to as the independent components of the observed data, which can be found by ICA.

Applications

Table 2 summarizes some applications relying on unsupervised learning assisted network association schemes. To elaborate a little further, clustering is a common problem in wireless networks, especially in heterogeneous scenarios associated with diverse cell sizes as well as Wi-Fi and D2D networks. For example, the small cells have to be carefully clustered for avoiding interference using coordinated multipoint transmission, while the mobile users are clustered for obeying an optimal offloading policy; the devices are clustered in D2D networks for the sake of achieving high energy efficiency; the Wi-Fi users are clustered for maintaining an optimal access point association, etc. A mixed integer programming problem was formulated for jointly optimizing both the gateway partitioning and the virtual channel allocation based on classic k -means clustering, which was employed for partitioning the mesh access points into several groups in a hybrid optical/wireless network scenario for the sake of reducing the overall wireless tele-traffic by encouraging the utilization of the high-capacity optical infrastructure (Xia et al. 2012). In Hajjar et al. (2017), a K -means-based relay selection algorithm was proposed for creating low-power small cells in an LTE macro cell within a multi-cell scenario, where the network's total capacity was increased without the need of additional infrastructure.

Both the PCA and ICA constitute powerful statistical signal processing techniques devised for recovering statistically independent source signals from their linear mixtures. One of their major applications may be found in the area of anomaly-, fault-, and intrusion-detection problems of wireless networks, which rely on traffic monitoring. Furthermore, similar problems may also be solved in sensor networks, mesh networks, etc. They can also be invoked for the physical layer signal dimension reduction of massive MIMO systems or for classifying

the primary users' behaviors in cognitive radio networks. In Qiu et al. (2011), PCA and ICA were applied in a smart grid scenario for recovering the simultaneous wireless transmissions of smart utility meters installed in each home, which were capable of enhancing both the transmission efficiency by avoiding the channel estimation in each frame and the data security by eliminating any wideband interference or jamming signals. Another pertinent example is found in cognitive radio scenarios, where the so-called Boolean ICA relied on the Boolean mixing of OR, XOR, and other functions of binary signals (Nguyen et al. 2013), where an iterative algorithm, termed as the binary ICA, was developed for determining the activities of the underlying latent signal sources, such as the PUs. It was demonstrated that given m monitors or SUs, the activities of up to $(2m - 1)$ distinct PUs can be inferred.

Reinforcement Learning in Network Association

Models

Multiarmed bandit relies on a player at a row of slot machines who has to decide which machines to play on and how many times to play on each. He/she will receive a random reward provided by the selected machine. The objective of the game is to maximize the sum of rewards earned through a sequence of lever pulls. It has become one of the popular examples of sequential decision-making

problems striking an exploration-exploitation trade-off relying on limited information.

Markov decision process (MDP) provides a mathematical framework for modeling decision-making in specific situations, where the outcomes are partly random and partly under the control of a decision-maker. At each time step, the process is in some state S , and the decision-maker may opt for any of the legitimate actions A that is available in state S . The process responds at the next time step by randomly moving into a new state S' and giving the decision-maker a corresponding reward $r(S, A)$. The probability that the process moves into its new state S' is influenced both by the specific action chosen and by the system's inherent transitions. As an important member of MDP family, *partially observable Markov decision process* (POMDP) may be suitable for a general scenario, where the agent is unable to directly observe the underlying state transitions and hence only has partial knowledge. The agent has to keep track of both the probability distribution of the legitimate states, based on a set of observations, and the observation probabilities and of the underlying MDP.

Q-learning may be invoked for finding an optimal action policy for any given finite Markov decision process, especially when the system model is unknown. It is a model-free reinforcement learning technique, and as such it can be used in conjunction with MDP models. In such a case, the Q-learning model is also comprised of an agent, of the states, and of a set of actions per state. By executing an action in a

specific state, the agent gleans a reward and the goal is to maximize its accumulated reward. Such a reward is illustrated by a Q -function, where “ Q ” is initialized to be a fixed value. Then, “ Q ” is updated in an iterative manner after the agent carries out an action and observes the resultant reward as well as the associated new state at each time instant.

Applications

Table 3 lists a range of applications of reinforcement learning assisted network association schemes. Generally, multiarmed bandit may be beneficially used in multiplayer adaptive decision-making problems, where selfish players infer an optimal joint action profile from their successive interactions with a dynamic environment and finally settle at some equilibrium point. This problem has indeed been encountered in many wireless networking scenarios, with a compelling one being the channel selection problem (Maghsudi and Stańczak 2015) and another one in the context of access point (AP) selection problem (Wang et al. 2018). Specifically, every mobile user was modeled as a player of the multiarmed bandit game, while the channels/APs were regarded as arms and choosing a channel or an AP corresponds to pulling an arm. The authors of Maghsudi and Stańczak (2015) proposed a channel selection strategy consisting of two main blocks for D2D communication system integrated into a cellular network, namely, the calibrated forecasting and the no-regret bandit learning strategies. Moreover, the authors of Maghsudi

and Stańczak (2015) proposed a multiarmed bandit-aided AP selection algorithm for a visible light communication (VLC) and Wi-Fi hybrid system (Li-Fi).

The family of MDP/POMDP models constitutes ideal tools for supporting decision-making in wireless networks, where the users may be regarded as agents and the network constitutes the environment. For instance, in Aprem et al. (2013), the transmission power control problems in energy harvesting wireless sensor networks (WSN) were investigated using the POMDP model, where the state space was defined by including the battery state, the channel state, the packet transmission/reception states, and an action by the node, which corresponded to sending a packet at a certain power level. In Wang et al. (2016), a POMDP-aided AP section algorithm was proposed for improving the energy efficiency of the super Wi-Fi system, including a low-complexity energy function-based solution.

Q-learning has also been extensively applied in HetNets, usually in conjunction with the aforementioned MDP models. In Alnwaimi et al. (2015), the authors presented a heterogeneous fully distributed multi-objective strategy based on a reinforcement learning model constructed for the self-configuration/optimization of femtocells. The model was supposed to solve both the resource allocation and interference coordination problem in the downlink of femtocell networks under carefully constructed restrictions for avoiding interference and for meeting the quality of service (QoS) requirements. Furthermore,

in Chen et al. (2009), a fuzzy Q-learning admission control for wideband code division multiple access (WCDMA)/wireless local area network (WLAN) HetNets was proposed, which considered not only QoS requirements but also multiple system measures, such as interferences, the numbers of real-time and non-real-time users, user’s mobility, etc.

Deep Learning in Network Association

Models

Artificial neural networks are a set of algorithms inspired by the biological neural networks that constitute animal brains, which help us cluster and classify. The *deep neural network* (DNN) is a kind of artificial neural network, with multiple layers between the input and output layers, which can model complex nonlinear relationships. The layers are made of nodes, where a node is just a place where computation happens, loosely patterned on a neuron in the human brain. A node combines input from the data with a set of weights that either amplify or dampen that input, thereby assigning significance to inputs for the task considered. The nodes residing in “deeper” layer of the neural net are capable of recognizing more complex features, since they aggregate and recombine features from the previous layer. In other words, the extra layers enable composition of features from lower layers, potentially modeling complex data with fewer units than a similarly performing shallow network.

The *recurrent neural network* (RNN) is another class of artificial neural network where

connections between units form a directed cycle, which allows it to exhibit dynamic temporal behavior. Unlike traditional neural networks where all inputs are independent of each other, RNN is called “recurrent” because they perform the same task for every element of a sequence, with the output being depended on the previous computations. Hence, RNN can be viewed to have a “memory” which captures information about what has been calculated so far. RNNs can use their internal memory to process arbitrary sequences of inputs.

Applications

In Table 4, we summarize some typical applications of deep learning aided network association algorithms. DNN algorithms are readily used for traffic control, wireless localization, activity recognition, resource allocation, and anomaly detection. Specifically, in order to improve traffic control in HetNets, the authors in Kato et al. (2017) first characterized the HetNet traffic and then proposed a supervised DNN system, which exploited the extracted characterizations to achieve excellent signaling overhead, throughput, and delay. Moreover, in a cognitive radio network, the DNN-based algorithm was proposed to learn features that indicated the influence of the target on the wireless signals, which substantially improved wireless localization and activity recognition (Wang et al. 2017a).

Furthermore, RNN can be applied to traffic classification, interference cancellation, and channel equalization. For instance, in Lopez-Martin et al. (2017), a combination model of a RNN and a convolutional neural network (CNN) was proposed to classify both the traffic and the

Machine Learning Paradigms in Wireless Network Association, Table 4

Applications of deep learning aided network association algorithms

Method	Scenario	Applications	Reference
DNN	HetNets	Traffic control	(Kato et al. 2017)
	Cognitive radio	Wireless localization	(Wang et al. 2017a)
	Smart grid	Attack detection	(He et al. 2017)
	WSN	Sensor calibration	(Wang et al. 2017b)
RNN	IoT network	Traffic classification	(Lopez-Martin et al. 2017)
	MIMO	Interference cancellation	(Mostafa 2017)
		Channel equalization	(Zhao et al. 2011)
	Cellular network	Power control	(Chen et al. 2006)

behavior of heterogeneous devices and services in IoT networks, which provided a superior detection result without requiring any feature engineering. Besides, as discussed in Mostafa (2017), RNN was beneficially invoked for interference cancellation in MIMO systems. The proposed RNN algorithm showed good performance in terms of suppressing impulsive noise while assuring the Lyapunov stability simultaneously.

Conclusions

This entry reviewed the benefits of artificial intelligence-aided wireless systems equipped with machine learning. We introduced the major families of machine learning algorithms and discussed their applications in the context of massive MIMOs, the smart grid, cognitive radios, HetNets, small cells, D2D networks, etc. The classes of supervised, unsupervised, reinforcement, and deep learning tools were investigated, along with the corresponding modeling methodology and possible future applications in wireless network association. In a nutshell, machine learning is an exciting area for artificial intelligence-aided networking research!

Definition

The machine-type communication (MTC) is a new type of communication technologies for the machine-to-machine (M2M) or Internet of Things (IoTs) with few or without human intervention (3GPP 2014), and it is proposed by the Third Generation Partnership Project (3GPP) working group.

Historical Background

The standardization work for the MTC was started by 3GPP TSG SA1 working group in early 2005. In 2007, a technical report on facilitating M2M communication in the 3GPP systems was exported (3GPP 2007). The 3GPP also identified the service requirements and system improvements for the MTC in release 10 (3GPP 2014), and a specific protocol implementation is described in release 11 (3GPP 2012).

The features of MTC specified by the 3GPP are listed as follows (3GPP 2014):

- Low mobility: The MTC devices have low mobility or move only within a specific area.
- Time controlled: The MTC devices transmit the data during specific time intervals.
- Small data transmissions: The applications have a small amount of data transmission or reception.
- Mobile originated only (or infrequent mobile terminated): Most of application calls are initiated by the MTC device.
- MTC monitoring: Most of applications monitor the behaviors and the events of the MTC devices.
- Priority alarm: The alerting function in applications reports anomaly events, e.g., the MTC devices were stolen or destroyed.
- Group-based MTC features: The system is optimized with grouped MTC devices.

Figure 1 shows the architecture of the MTC in release 11 (3GPP 2012, 2018), where an MTC device connects to the LTE core network through the LTE-Uu air interface. The network entities and interfaces are described as follows:

- The MTC Interworking Function (MTC-IWF) is a network element that receives external application service signaling through the Tsp interface.
- The Service Capability Server (SCS) communicates with MTC devices through the MTC-IWF. The MTC devices can access one or more application services controlled and

managed by the Application Servers (ASs) through the SCS.

- The S6m interface exercises between the MTC-IWF and the Home Subscriber System (HSS). The interface is used by the MTC-IWF to obtain the IDs of an MTC device from the HSS, which include the International Mobile Subscriber Identity (IMSI) and Mobile Subscriber Integrated Services Digital Network Number (MSISDN).
- The MTC-IWF sends trigger messages to the Short Message Service Center (SMS-SC) through the T4 interface.

Based on the above network architecture, the 3GPP defines three modes for the core network to connect to the MTC ASs, including the indirect mode, the direct mode, and the hybrid mode. The executions of the three connected modes are described below:

- Indirect mode: The AS connects to the core network through the SCS.
- Direct mode: The AS connects the core network through the PDN Gateway (P-GW) that is a router in the core network and provides IP connectivity between the core network and external data network.
- Hybrid mode: The LTE network operator can provide both of indirect and direct modes.

Key Applications

The 3GPP release 14 (3GPP 2017) lists the key applications that fall into the following service areas.

- The following MTC applications belong to the security service area:
 1. An alarm system includes a set of MTC devices that can trigger an alarm. Examples of the MTC devices can be gas sensors, temperature sensors, etc.
 2. A surveillance system uses the MTC devices (e.g., camera, closed-circuit

Machine-Type Communication, Fig. 1 The architecture of LTE MTC network

television; CCTV) to observe or monitor users' behaviors and activities.

3. The backup-for-landline system is usually used for home security, which is equipped with the MTC devices to monitor the land-line. If the landline is broken, the MTC devices will send a warning message to the monitor system and notify that the landline has something wrong and needs to fix.
 4. The physical access control system accommodates a set of physical equipment (e.g., RFID door and gate controller). The physical access control system is implemented in a building and authorizes legal access.
 5. With the car/driver security system, in a connected vehicle, the MTC devices can retrieve the information (e.g., revolution per minute; RPM), based on which, the system can diagnose whether the car is safe or not. It also ensures the safety of the driver.
- The following applications fall into the tracking and tracing service area:
 1. With the fleet management system, a car installed with the MTC devices which combine GPS and short message service to keep track immediate location and history trajectory of a car.
 2. In the pay-as-you-drive service, the car insurance fees are easy to collect based on the information in car such as speed, history trajectory, and driving time, and then the collected data transmit to the insurance company.
 3. With the asset tracking system, every asset installs an MTC device with GPS service, and the MTC device sends the location to the asset tracking system for easy tracking the location of the asset.
 4. In the navigation service, the drivers can change the driving path in advance through the geographical information and other information reported by the MTC devices to avoid the traffic jams.
 5. With traffic information system, the car equips with MTC devices combined GPS function that reports location information

- to the MTC server. Then, based on the reported location, the MTC server provides the traffic information of that of reported location to inform driver to avoid the traffic jam.
6. With the road tolling system, the roadside units (RSUs) are deployed along the free-way. When a car equipped with the MTC device passes by that of the freeway, the RSU senses the equipped MTC device and then makes a charge.
 7. With the traffic optimization/steering system, based on the location collected by MTC device in a car, it is easy to provide the guideline to the driver to achieve the traffic optimization and steering.
- The following MTC applications belong to the payment service area:
 1. With the point-of-sales system, the MTC device reads commodity information (e.g., good name, price, and qualify) and then sends the information to relevant departments through communication networks for analysis to improve operating efficiency of the system.
 2. The vending machine system is equipped with MTC devices to inform the sales that the items have been sold out by email or short messages, and they should replenish the items immediately. Another application is if the vending machine is broken down, the MTC device is triggered to send an alert (e.g., short message) to the sales.
 - The following applications fall into the health service area:
 1. With the monitoring vital signs system, the person wears MTC devices that monitor the changing of vital signs (e.g., the pulse, temperature, breathing, and blood pressure). If the monitoring vital signs change, the MTC devices send an alert message to the monitoring vital signs system.
 2. In the aged and handicapped system, the MTC devices are deployed in the home environment to keep track of the behavior of elderly people.
 3. With the remote health diagnostics system, the doctor can remotely monitor the health status and chronic conditions of patients anywhere anytime through the MTC devices and make reaction immediately when an emergency event occurs.
 - The following applications fall into the remote maintenance and control service area:
 1. In the programmable logic controllers (PLCs) system, MTC devices can control PLC by predefined instructions (e.g., turning on the light at home) which are stored in PLCs memory.
 2. In the sensor system, the MTC devices are deployed as sensors (e.g., power, fire, smoke, gas, water, wind, etc.) to monitor the environment.
 3. In the lighting system, the MTC devices can detect environmental change (e.g., from day to night) and send a notification to the lighting system to turn on the light.
 4. In the vending machine control system, the vending machine is installed with MTC devices to determine whether the vending machine operates normally or abnormally. If the detected result is abnormal, the MTC devices send a warning message to the vending machine control system.
 5. In the vehicle diagnostics system, the MTC devices are installed in a connected car to collect the information from the car, and then send the information to the vehicle diagnostics system, based on which the diagnostics system analyzes whether the car is in the safe status or the dangerous status.
 - The following MTC applications belong to the metering service area:
 1. In the gas system or the water system, the MTC devices are installed as smart meters,

which collect the information about the usage of gas or water. The information is referenced to charge the users for the usage of gas or water.

2. In the heating system, the MTC devices are deployed as sensor to sense the ambient temperature to control the heating automatically.
3. In the grid control system, the MTC devices collect information of power supply status in the home environment, and send the information to the grid control system to adjust the production and transmission of electricity to reduce the power consumption for power saving.

Maritime University, Dalian, China

Synonyms

[Internet of Things for vessels](#); [Networking of marine vessels](#)

Definitions

Maritime Internet of Vessels is a kind of information service network for intelligent shipping which integrates Internet of Things technology. It takes vessels, waterways, and land-shore facilities as basic nodes and information sources and connects vessels through wireless communication technology, aiming at realizing the refinement of shipping management, the comprehensiveness of industry services, and the humanization of user experience.

Key Points

Historical Background

With the development of shipping industry, the amount of data and information acquired from

ships, cargo, operators, and navigation environment is increasing at the speed of TB and PB, and the traditional maritime communication systems can hardly afford for the development requirements at present. How to transmit, store, and manage the massive data effectively has become a research hotspot. At present, more than 80% of the world's trade is completed by shipping, and more than 50,000 merchant ships are engaged in international trade, maintaining the stability of global material transport. However, accidents related to navigation continue to occur despite the development and availability of a number of ship- and shore-based technologies that promise to improve situational awareness and decision-making. In 2018, there were 255 pirate attacks and harassment incidents worldwide, and 126 crew members were kidnapped by pirates worldwide. Safety, efficiency, and environmental protection of maritime communications have always been the core issues in the development of intelligent shipping, as well as the key points in ship collision avoidance, navigation assistance, and maritime positioning.

In recent years, the “intelligent” manufacturing model and products have extended to various fields, and many high tech and equipment have been greatly developed and widely used in the field of navigation, especially on board ships. “Intelligent shipping” and “e-Navigation” are respectively promoted on two independent main lines of development to jointly realize the safety, efficiency, and environmental protection of maritime shipping. In addition, the Maritime Internet of Vessels will bring shipping into a new era in which vessels and vessels, vessels and waterways, and vessels and people are interconnected and the original risk-ridden and uncertain voyages begin to become intelligent and controllable. To better comprehend the development of the Maritime Internet of Vessels, this entry makes a detailed investigation about the existing networking modes for Maritime Internet of Vessels and puts forward the further development. With different kinds of possible network access and interconnection, the ubiquitous links between vessels and vessels and people can be realized; the intelligent perception, recognition,

and management of vessels and processes can also come true; and the maritime navigation will become more intelligent, controllable, safe, and environmentally friendly.

The Existing Networking Modes for Maritime Internet of Vessels

At the 81st meeting of the Maritime Safety Committee (MSC) of the International Maritime Organization (IMO), an e-Navigation proposal was put forward jointly in order to integrate and harmonize the maritime communication systems and better exchange and unify information between shore-based and shipboard users through electronic means. The IMO has defined e-Navigation as “the harmonized collection, integration, exchange, presentation and analysis of marine information on board and ashore by electronic means to enhance berth to berth navigation and related services for safety and security at sea and protection of the marine environment” (Weinrit and Weinrit 2011). The establishment of e-Navigation makes the information exchange between ship and ship and ship and shore safer, more convenient, and more efficient. On this basis, the concept of Maritime Service Portfolios (MSP) came into being which mainly refers to a set of standardized, operational, and technical maritime service information provided by the coastal side to navigators in a given sea area, waterway, port, and other similar areas. According to different applications and services, the networking modes for Maritime Internet of Vessels will be described from the perspective of conventional communications and emergency communications:

- **The conventional communications**

The conventional communications are mainly used for maritime applications such as electronic chart display and information system (ECDIS), normal navigation, voyage planning, crew and passengers' communications, etc. These systems mainly operate at medium- and high-frequency systems and very-high-frequency (MF, HF, VHF) band to achieve a certain degree of voice and data communication.

- (1) Digital selective calling (DSC) (MF/HF & VHF bands)

Digital selective calling or DSC is a standard for sending pre-defined digital messages to another station or group of stations for distress or general communications via the medium-frequency (MF), high-frequency (HF), and very-high-frequency (VHF) maritime radio systems (de Sousa and Pelas 2011). The International Radio Advisory Committee (CCIR) has allocated a DSC channel in the 2 MHz band of MF; the 4, 6, 8, 12, and 16 MHz band of HF; and the VHF marine channel 70 (156.525 MHz) for the DSC distress call (alarm) frequency and the radio telephone, radio distress, and secure communication frequency.

- (2) Narrowband direct printing (NBDP or radio telex, MF)

NBDP is a technology that automates radio signals to telegraphy which has been used for ship location reporting and the issuance of weather warnings and forecasts at coastal stations, while the use of NBDP for general communications is decreasing. As an integral part of GMDSS, NBDP is a FSK modulated to 0.5 kHz HF channel, which supports low-speed data transmission (100 bps) over 1.6–26.5 MHz for maritime mobile services. It can be used as text-based distress tracking communication and general communication between ship-to-ship, ship-to-shore, and shore-to-ship, especially to overcome language difficulties.

- (3) Navigational Telex (NAVTEX, MF)

NAVTEX (Navigational Telex), as a major element of the global maritime distress and safety system, is diffusely used for delivery of navigational and meteorological warnings and forecasts, as well as urgent maritime safety information to ships. It mainly provides a low-cost, simple, and automated means of receiving this information aboard ships

at sea within approximately 370 km off shore. It adopts FSK modulation scheme and broadcasts messages in English on MF band of 518 kHz, while 490 and 4209.5 kHz are used to broadcast in English and/or local language.

- (4) Automatic identification system (AIS, VHF)

The automatic identification system (AIS) is an automatic tracking system aimed at improving the safety of navigation by assisting ships in effective navigation, environmental protection, and operation of vessel traffic services (VTS). It provides a means for ships to electronically exchange ship data including identification, position, course, speed and navigational status with other nearby ships and AIS base stations, and satellites. AIS uses VHF channels and adopts a technology called self-organized time division multiple access (SOTDMA) to ensure that the VHF transmissions of different transceivers do not occur at the same time. Besides, AIS is also integrated into other maritime devices such as aids to navigation (A to N), search and rescue transmitter, and man overboard units (Lázaro et al. 2017).

- (5) VHF data exchange system (VDES, VHF)

VDES is an enhanced and upgraded system of AIS for alleviating the pressure in the existing frequency band of the AIS system and ensuring the implementation of the normal function in the field of maritime mobile services. On the basis of integrating existing AIS functions, VDES adds special application message (ASM) and broadband VHF data exchange (VDE) functions, which can effectively alleviate the pressure of existing AIS data communication and provide effective auxiliary means for the protection of ship navigation safety. At the same time, it will comprehensively improve the ability and frequency efficiency of marine data communication, which is of great significance to promote the development

of marine radio digital communication industry. Furthermore, the standardization process of VDES is quite mature, and it is expected to become an ITU standard soon (Lázaro et al. 2017).

- The emergency communications

Besides general communications, the emergency communications also focus on security issues of maritime applications which are related to the safety of life and property at sea, distress and urgency alerting/calling, collision avoidance, long-range identification and tracking (LRIT), etc. The typical systems are the global maritime distress and safety system (GMDSS), the global navigation satellite systems, and the marine satellite communication systems.

- (1) GMDSS

The global maritime distress and safety system (GMDSS), described in the Safety of Life at Sea (SOLAS) Chapter IV Convention, is an immense integrated global communication network mainly composed of three parts: satellite communication systems (INMARSAT (International Maritime Satellite Organization) and COSPAS-SARSAT (Global Satellite Search and Rescue System)), terrestrial radio communication systems (i.e., coastal radio station), and maritime safety information broadcasting systems. Figure 1 shows its concept map. The system is intended to perform the following functions: alerting (including position determination of the unit in distress), search and rescue coordination, locating, maritime safety information broadcasts, general communications, and bridge-to-bridge communications. Once distress alerts appear, onshore search and rescue agencies and nearby shipping departments will promptly issue alerts through satellite communications and ground communications technology so that they can assist

in coordinating search and rescue operations. According to the GMDSS, all cargo or passenger ships with a total tonnage of 300 or more must be equipped with radio equipment that conforms to international standards which guarantees maritime safety to a certain extent.

- (2) The global navigation satellite systems

The global navigation satellite systems (GNSS) is a space-based radio navigation and positioning system that uses satellites to provide autonomous geo-spatial positioning on the earth's surface or near-Earth space. It can be used for providing position and navigation or for tracking the position of something fitted with a receiver (satellite tracking) which is widely applied for the safety of maritime navigation. Common systems include the United States' Global Positioning System (GPS), Russia's GLONASS, China's BeiDou Navigation Satellite System (BDS), and the European Union's GALILEO. Table 1 shows the details.

- (3) The marine satellite communications

The marine satellite communications in the UHF band have global or regional coverage and are commonly deployed on ships and vessels to fulfill different communication requirements despite their high cost. As the commercially provided services, they can implement multiple communication services (voice, data, e-mail, SMS, crew calling, telex, facsimile, remote monitoring, tracking (position reporting), etc.) to guarantee the normal operation of daily cruise and satisfy the needs of crew members to contact with their families. According to the status of satellites, they can be geostationary or non-geostationary. Worldwide, typical marine satellite communication systems mainly include VSAT, Inmarsat systems,

iridium satellite system, etc. Table 2 mainly summarizes the correlative systems widely employed in maritime communication.

In addition, it should be noted that as a supplement to conventional communications and emergency communications, coastal mobile communications mixing with cellular or other wireless communication technologies have unique communication advantages in offshore areas. The off-shore coverage of these shore-based communication systems could provide reliable communication guarantee for ports, wharfs, channel manage-

ment, mariculture, and salvage at sea (Minghua et al. 2017), such as GSM/GPRS, 3G, 4G, Wi-Fi, WiMAX, mesh networks, ad hoc networks, and short-range devices like ZigBee and Bluetooth links. Although they could offer higher transmission rate, the communication distance is limited in range. A heterogeneous network integrated with above communication technologies is shown in Fig. 2.

Further Development

Currently, with the high development of maritime industry and activities, the demand for maritime communications services is increasing, which

Maritime Internet of Vessels, Fig. 2 A heterogeneous network for Maritime Internet of Vessels

puts forward higher requirements for the safety, reliability, and effectiveness of maritime communications. The traditional communication systems can hardly afford for the extreme volume of data generated by navigation services, video monitoring, and multimedia downloading, and new technologies and schemes are in the pipeline. Following the Internet of Things and Internet of Vehicles, the Maritime Internet of Vessels has come into people’s vision. Maritime autonomous surface ships (MASS) are playing

a very important role in the development of Maritime Internet of Vessels, and many new technologies are being explored to enhance the communication efficiency for the Maritime Internet of Vessels.

• MASS

In recent years, ship intellectualization has become the general trend of global intelligent shipping. In order to reduce the difficulty of ship control and management, reduce

man-made misoperation, improve the safety of equipment and ship operation, optimize ship navigation, reduce costs, and increase profits, the research on MASS has been carried out worldwide (<http://www.sumia.org/newsdetails.aspx?id=2760>).

According to the definition of “intelligent ship specification” promulgated by China Classification Society (CCS) in 2016, “intelligent ships” refers to the use of sensors, communications, Internet, and other technical means to automatically perceive and obtain information and data of the ship itself, marine environment, logistics, ports, and other aspects. Based on computer technology, automatic control technology, and large data processing and analysis technology, the intelligent operation of ships in the aspects of navigation, management, maintenance, and cargo transportation should be realized, so as to make the ships safer, more environmentally friendly, more economical, and more reliable. The functions of intelligent ships are composed of intelligent navigation, intelligent hull, intelligent engine room, intelligent energy efficiency management, intelligent cargo management, and intelligent integrated platform (https://blog.csdn.net/weixin_37978606/article/details/80957137). Figure 3 summarized four development phases for MASS. Now it is in the transitional stage from the first phase to the second phase, and the fourth phase is the era of full automation.

In order to realize the full intellectualization of ships, there are still many problems that had to be overcome. First of all, the communication volume is large because of the need to transmit a large number of sensor information and equipment status information, as well as radar images, sea video, and so on. The maritime communication systems should be able to fulfill the requirements of high bandwidth, low delay, low cost, etc. Besides, adequate attention should be paid to the maritime network security. With the increasing of ship-shore communication, more and more ships are exposed which makes the security

of maritime communication systems becomes increasingly important. How to avoid hacker attacks, key information leaks, and emergency plans of MASS in network attacks are all issues that need further study.

- Application of new technologies

With the refinement, comprehensiveness, and humanization of ship management, the amount of data is increasing rapidly. How to store and manage massive data effectively has become more and more important. The establishment of Maritime Internet of Vessels needs to be data-centric, combined with Internet technologies and Internet of Things technologies, to realize the interconnection between vessels and vessels, people and vessels, vessels and cargo, and vessels and shore-based facilities. For example, the fog/edge computing, information perception and interaction technologies, and big data fusion and analysis technologies can be applied in the field of Maritime Internet of Vessels.

- (1) Fog/edge computing

Currently, continuous development of maritime business has fuelled faster growth in the amount of data and information acquired from ships, cargo, operators, and navigation environment. It has become increasingly important to achieve effective transmission, storage, and management of these massive data although they require massive computing resources, storage space, and communication bandwidth. As an extension of cloud computing, fog/edge computing can be employed to extend computing, storage, and networking resources to the network edge and alleviate the heavy burden of large amounts of data on the network (Ni et al. 2018).

- (2) Information perception and interaction technology

The application of Maritime Internet of Vessels cannot be separated from the support of information sensing technology. With the increasing concentration of maritime traffic routes, the increasing total

Maritime Internet of Vessels, Fig. 3 Development of MASS (<http://www.sumia.org/newsdetails.aspx?id=2760>)

number of vessels, and the sharp rise of communication equipment, information transmission and interaction between different equipment become more and more important, which puts forward higher requirements for information collection, identification, management, and integration. In order to reduce information redundancy and error, improve the information system of ship networking, and improve the intelligent level of Maritime Internet of Vessels, it is necessary to strengthen the research of information perception and interaction technology.

(3) Software-defined network

SDN (software-defined network) is a new network architecture, which can separate network control from traditional hardware devices. Since most of the maritime communication nodes are in motion, the business environment of the network is constantly changing. For the traditional network, if the business needs change, it is quite tedious to modify the configuration of network equipment. Therefore, in order to better meet the special requirements of Maritime Internet of Vessels, the flexibility and agility of the network become more and more important, and SDN can be taken into account to address such issues.

(4) Big data analysis technology

With the continuous development of maritime communications, marine information sensing and communicating equipment, which covers a variety of information transmitting means such as acoustic, optical, and electromagnetic, is continuously generating massive data which have shown the characteristics of huge volume, various data types, fast flow speed, and high value (You and Wei 2018). How to analyze and process these data and improve the breadth and depth of data utilization is a critical issue. It is urgent to strengthen the research of big data analysis technologies, so as to promote the rapid development of Maritime Internet of Vessels.

In addition, the layout of customized systems for Maritime Internet of Vessels should be accelerated, the integration of ship-shore intelligent information should be realized, and a visual sharing platform of information for Maritime Internet of Vessels to ensure the safety of ship navigation and intra-ship communication can also be taken into account. At the same time, the goals of saving energy, reducing operation and maintenance costs, and improving operational efficiency can be achieved. With all kinds of possible network access and interconnection, the ubiquitous links

between vessels and vessels and people can be realized; the intelligent perception, recognition, and management of vessels and processes can also come true, which makes vessels and vessels, vessels and waterways, and vessels and people more interoperable; and the maritime navigation will become more intelligent, controllable, safe, and environmentally friendly.

Conclusion

With the development of shipping industry, the amount of data and information acquired from vessels, cargo, operators, and navigation environment is increasing, and the traditional maritime communication systems can hardly fulfill the development requirements at present. This entry makes a detailed investigation about the existing networking modes for Maritime Internet of Vessels and points out the further development. In 5G era, great efforts should be made to connect more information units for Maritime Internet of Vessels and provide more information sharing services through real-time interconnection, and then the development of intelligent shipping can be further promoted, so that the safety and efficiency of shipping become predictable.

[Market entry strategy](#)

Definitions

Market entry is the activities associated with bringing a product or service to a targeted market. A market can denote the *primary market* and *secondary market*. The *primary market* refers to the market where the companies sell new products to the customers for the first time, while the *secondary market* is one in which the customers trade the products among themselves.

Historical Background

As the rapid development of the wireless technology, numerous wireless-related services (e.g., 4G wireless service, femtocell service, mobile data trading service) are emerging. When facing the new services, asymmetric behaviors of the wireless service providers (WSPs) and users are observed. For example, the providers may have different timing of introducing the new wireless

services to the market, and the heterogeneous users have different response to these services. Game theory provides solid mathematic tools for analyzing the behaviors of providers and users in wireless networks (Han 2012). One of the most popular examples of game theory in wireless networks is the power control problem, where the transmit power level of a wireless user can pose a positive or negative impact on the transmission rate and quality of service (QoS) of the other users due to interference. By noting the competition between the users, Shah et al. (1998) first formulate the interactions of wireless users as a non-cooperative game and obtain the equilibrium transmit power of all users. Following the pioneer work on non-cooperative games in power control, game theory has been implemented to plenty of application areas in wireless network market entry, e.g., the adoption of femtocell service (Shetty et al. 2009; Yun et al. 2011), new wireless technology introduction (Sen et al. 2010), and secondary mobile data trading market (Zheng et al. 2015; Wang et al. 2016). Musacchio et al. (2006) develop a game theoretic model for studying the upgrade timing of two interconnected Internet service providers (ISPs), where the network upgrade of one ISP has positive network effect on the other. This “free-rider” effect makes it reluctant for the providers to upgrade and instead enjoy the benefits of other providers’ upgrading. Duan et al. (2015) further discuss the upgrade timing of 4G network by taking the user churn into consideration, which weakens the free-riding effect. When introducing new technologies to the network, the competition between entrant and incumbent network technologies may exist. Dynamic games can be used to analyze the users’ adoption dynamics of a new network technology in the presence of an incumbent technology (Sen et al. 2010). To understand the interactions between the providers and their users, Stackelberg games provide an ideal tool to study the hierarchical decision-making among the players, in which the providers (leaders) declare and announce their strategies first and then the users (followers) react selfishly based on the strategies of the providers. Using non-cooperative Stackelberg games, Duan et al. (2013, 2016) study the

economic incentive for an operator to introduce the femtocell service on top of its existing macrocell service centrally and distributedly, in which users submit their bandwidth demands to the operator based on the service and corresponding price and the macrocell operator and femtocell operator (same in central case) can adjust the bandwidth price to maximize their profits. Wang et al. (2016) also use Stackelberg games to study a secondary market in which mobile data users are allowed to trade unused data.

Foundations

Game theory is a basic theory in economics used for the analysis of strategic decision-making of intelligent rational players. The normal-form representation of a game consists of three parts (Gibbons 1992):

- The game players $\mathcal{N} = \{1, 2, \dots, N\}$.
- The available strategy set S_i of each player $i \in \mathcal{N}$. Denote the strategy chosen by player i as $s_i \in S_i$ and the strategies of all players except player i as s_{-i} . Let $S = \prod_i S_i$ denote the set of all possible strategy profiles.
- The utility U_i received by player i for each possible combination of strategies $s \in S$.

Non-cooperative Games

There are many types of games possessing different properties suited for analyzing variety of situations. *Non-cooperative games* are used ubiquitously for the analysis of market entry in wireless networks, in which many players compete for finite resources and each player behaves selfishly and independently by maximizing his own utility, given the possible strategies of other players and their impact on the player’s utility (Osborne 2004). For example, the wireless providers compete over new wireless technologies and pricing strategies to attract users, and the users are involved in many non-cooperative situations such as allocation of bandwidth, transmit power, etc.

To describe the best strategy for a typical player under any given strategy profile of all

other players, the concept of *best response* is introduced.

Definition 1 For each player i , the best response is the strategy such that

$$BR_i(s_{-i}) := \{s_i \in S_i : U_i(s_i, s_{-i}) \geq U_i(s'_i, s_{-i}), \forall s'_i \in S_i\} \quad (1)$$

Nash equilibrium is the stable outcome of a game, which is defined as the strategy profile of all players where none of the players can improve its utility by a unilateral move.

Definition 2 A profile $s^* \in S$ is called a pure strategy Nash equilibrium, if for each player $i \in \mathcal{N}$:

$$U_i(s_i^*, s_{-i}^*) \geq U_i(s_i, s_{-i}^*), \quad \forall s_i \in S_i. \quad (2)$$

Stackelberg Games

In many non-cooperative games, a hierarchy among the players might exist where a fraction of the players (leaders) make decisions first and the rest of the players (followers) react selfishly based on the strategies of the leaders. This kind of games forms special classes of non-cooperative games called *Stackelberg games*, which is widely used in economic literature (He et al. 2007).

For a two-stage Stackelberg game, let $\mathcal{N}_L$ denote the set of leaders who announce their strategies first at Stage I and $\mathcal{N}_F$ denote the set of followers who make decisions accordingly at Stage II. Let $s_{i,L}$ denote the strategy of leader $i \in \mathcal{N}_L$ and s_L denote the strategy profile of all leaders. Let $s_{i,F}$ denote the strategy of follower $i \in \mathcal{N}_F$ and s_F denote the strategy profile of all followers. Then, the concept of Stackelberg equilibrium can be characterized as follows.

Definition 3 A profile $\{s_L^*, s_F^*\} \in S$ is a Stackelberg equilibrium strategy, if for each follower $i \in \mathcal{N}_F$:

$$U_i(s_{i,F}^*, s_{-i,F}^*, s_L^*) \geq U_i(s'_{i,F}, s_{-i,F}^*, s_L^*), \quad \forall s'_{i,F} \in S_i, \quad (3)$$

and for each leader $i \in \mathcal{N}_L$:

$$\begin{aligned} &U_i(s_{i,L}^*, s_{-i,L}^*, s_F^*(s_{i,L}^*, s_{-i,L}^*)) \\ &\geq U_i(s'_{i,L}, s_{-i,L}^*, s_F^*(s'_{i,L}, s_{-i,L}^*)), \\ &\forall s'_{i,L} \in S_i. \end{aligned} \quad (4)$$

Generally, the non-cooperative Stackelberg game is used to analyze the strategic interaction between the wireless providers (who decide the market entry timing and pricing of the services) and wireless users (who decide whether to subscribe to the new services and how much to buy based on their utilities) in the wireless market.

Key Applications

Network economics and pricing can be used to model and analyze many market entry problems in wireless networks. Some key applications are summarized in the following.

Market Entry Timing of New Technologies

As with the emergence of new technologies in wireless networks, the wireless providers should decide whether to deploy the new technology to improve the QoS and the upgrade timing. Generally, the cost of new technology upgrade decreases over time as the technology matures. An existing user can switch to the new technology service of the same provider or a different provider according to the switching cost. Being the first to upgrade to new technology, a provider increases its market share but spends more money on the upgrade. Therefore, the provider decides its upgrade time by trading off increased market share and upgrade cost.

Duan et al. (2015) study the upgrade timing of the fourth generation (4G) technology on the basis of third generation (3G) of cellular wireless networks by developing a game theoretic model for analyzing the competitive providers' interactions. The main results show that:

- When the upgrade cost is low, the 4G monopolist upgrades at the earliest available time; otherwise it postpones its upgrade.
- Under no inter-network switching case, i.e., no user switches operators due to high switching cost, competitive operators upgrade simultaneously, no matter how much the upgrade cost is.
- Under practical inter-network switching case, competitive operators select different upgrade times to avoid severe competition. By upgrading early, an operator captures a large market share and the 4G's QoS improvement which can compensate for the large upgrade cost. The other operator, however, postpones its upgrade to avoid severe competition and benefits from cost reduction. The availability of 4G upgrade may decrease both operators' profits because of the increased competition, and paradoxically, their profits may increase with the upgrade cost.

Secondary Service Entry

To improve the QoS and attract more users, the WSPs are eager to bring new technologies and services to the wireless market on top of the existing services, e.g., the introduction of femtocell service on top of the existing macrocell service. Femtocell technology is introduced to solve the poor signal reception problem for indoor users, as the high-frequency and low-power wireless signals from macrocell base stations often have difficulty in effectively traveling through walls. By bringing the femtocell service to the market, the macrocell operator should consider two main questions:

- Can the macrocell operator benefit from the femtocell service?
- How should the macrocell operator allocate and price the spectrum bands?

Users experience different channel conditions and spectrum efficiencies with the macrocell service, but all of them achieve a high spectrum efficiency with the femtocell service

by deploying a femtocell at home. Thus, users have different preferences between macrocells and femtocells and should decide which service to choose and how much bandwidth to request based on the price of each service.

The macrocell operator can provide the femtocell service itself or lease spectrum to a femtocell operator. For the situation when femtocells are managed by the same operator that controls the macrocells, Duan et al. (2013) model the interactions between the operator and users as a two-stage Stackelberg game. In Stage I, the operator determines bandwidth allocated to femtocell and macrocell service and the corresponding prices. In Stage II, each user decides which service to choose and how much bandwidth to purchase. It reveals that:

- If femtocell service has the same maximum coverage as macrocell service, the operator will choose to provide femtocell service only, as this leads to a better user quality of service and a higher operator profit.
- If all users have reservation payoffs which are what they can achieve with the original macrocell service, then the operator will always continue providing the macrocell service (with or without the femtocell service) to ensure that all users achieve payoffs no worse than their reservation payoffs.
- When multiple femtocells can reuse the same spectrum resource, the operator has more incentives to allocate spectrum to femtocell, and the femtocell price will be reduced. Moreover, when femtocell service incurs operational cost to the operator or has a smaller coverage than the macrocell service, the operator will always serve users by dual services. Furthermore, as cost decreases or coverage increases, more users are served by the femtocell service.

For the situation when the macrocell operator leases spectrum to independent femtocell operators, Duan et al. (2016) model the interactions between a macrocell operator, a femtocell operator, and end users as a three-stage dynamic game.

In Stage I, the macrocell operator decides bandwidth allocations to femtocell service and macrocell service and the macrocell price. In Stage II, the femtocell operator decides how much bandwidth to lease from the macrocell operator and the femtocell retail price. In Stage III, each user decides which service to choose and how much bandwidth to request. It reveals that:

- The macrocell operator has more incentive to lease spectrum to the femtocell operator when its spectrum capacity is small, as femtocell services can help cover more users and improve the utilization efficiency of the limited spectrum resource. Otherwise, the macrocell operator has less incentive to enable femtocell service due to the significant competition.
- In general, femtocell service can increase both the total consumer surplus and social welfare. However, some users who originally receive good service in macrocell might experience a payoff drop after the femtocell service is introduced, due to fewer resources being allocated to the macrocell service and a higher macrocell price.

Secondary Data Trading Market Entry

Another key application is the secondary data market entry for mobile data trading. In reality, a lot of data users subscribe to the data plans with certain amount of data quota which will expire in a billing cycle (e.g., 1 month). Some users can easily use up their data quota and may pay for costly data over-usage, while some users cannot use up their data quota and have leftover data. Motivated by users' diverse usage behavior (more or less than the subscribed data quotas), the secondary data trading market appears in which cellular users can trade data plans with each other, e.g., 2CM (2nd exchange market) data trading platform introduced by China Mobile Hong Kong. Yu et al. (2015), Zheng et al. (2015), and Yu et al. (2017a) discuss such a market, where data users submit bids to buy and sell data. The provider serves as the middleman to match buyers and sellers, as well as charges administration fees

and/or pockets the differences between the buyer and seller prices. Moreover, Yu et al. (2017b) study the mobile data trading problem under future data demand uncertainty. Taking the latest market and usage information into consideration, an algorithm is designed to help estimate the users' risk preference and provide trading recommendations dynamically. Wang et al. (2016) further propose a new type of user-initiated network for cellular users to freely trade data plans by leveraging personal hotspots (PHs) without the wireless provider's involvement. A user with data surplus can set up a PH and share the cellular data connection to another user with data deficit in the vicinity. Moreover, the WSP's countermeasures to the PH market and the competition between WSPs are investigated. Following this work, Wang et al. (2017) study the PH-enabled data-plan sharing between local users and travelers by taking into account the information uncertainty at the traveler side. Lacking the selfish PHs' information, the expected cost of the traveler is higher than that under the complete information, but the gap diminishes as the PHs' spatial density increases.

Future Directions

The economics of market entry can be applied to analyze the upgrading time and interactions between the WSPs and users for many new technologies and services, e.g., the introduction of 5G, smart home.

► Market Entry

Massive MIMO

Erik G. Larsson and Emil Björnson
Department of Electrical Engineering (ISY),
Linköping University, Linköping, Sweden

Synonyms

Full-dimension MIMO; Large-scale antenna systems (LSAS); Large-scale MIMO; Massive multiuser MIMO; Very large MIMO

Definition

Technology that uses large numbers of phase-coherently operating antennas at wireless base stations to serve a multitude of users by spatial multiplexing.

Historical Background

The wireless transmission from a single antenna has a predefined directivity, independent of where the users is located; see Fig. 1. The idea of using multiple antennas at wireless transceivers goes back a long time, at least to Alexanderson (1919), where analog transmit beamforming was used to direct the signal toward the receiving user and Peterson et al. (1931) where spatial diversity from receive beamforming was discussed. Modern incarnations of the idea have particularly included the concept of spatial-division multiple access (SDMA), proposed in the early 1990s by Swales et al. (1990), Anderson et al. (1991), and Roy and Ottersten (1991), and techniques for the suppression of interference using antenna arrays by Winters (1984). The novelty of these methods was to enable users to be multiplexed spatially,

Massive MIMO, Fig. 1 In single-antenna transmission, the transmission has a predefined directivity, independent of the location of the receiving user. One example is omnidirectional transmission, as shown in the figure

Massive MIMO, Fig. 2 In multiuser MIMO transmission with few antennas, the spatially multiplexed signals are broadly directed with beamforming toward the respective receiving users

Massive MIMO, Fig. 3 In Massive MIMO transmission, many users are spatially multiplexed with narrow beamforming, using an array of very many antennas

instead of in time or frequency, to increase the spectral efficiency of a wireless network; see Fig. 2.

Early attempts to efficiently utilize multiple transceiver antennas did not succeed well. There are many potential reasons for this: first, most methods made simplifying assumptions on the propagation environment that do not hold in practice; second, the hardware was not sufficiently advanced at the time; and, third, the corresponding information theory was not yet developed and hence important insights into the significance and difficulties in acquiring accurate channel state information were largely missing. An information-theoretic framework first took form in Caire and Shamai (2003), Goldsmith et al. (2003), and Viswanath and Tse (2003). Subsequently, SDMA became more commonly known as multiuser multiple-input multiple-output (MIMO), which reflects the fact that the

base stations have multiple antennas and there are multiple users.

Despite the mentioned difficulties, elementary forms of SDMA technology were successfully showcased in the mid-1990s by Anderson et al. (1996). ArrayComm in cooperation Kyocera made the first commercial deployment of SDMA as an overlay to the Personal Handyphone System (PHS) in a limited part of South-east Asia.

Foundations

Massive MIMO is an evolved and practically useful form of multiuser MIMO. The key concept is to use a very large number of phase-coherently operating antennas at the base station, as illustrated in Fig. 3. Since its inception in Marzetta (2010), it has quickly evolved from

a wild theoretical concept with an “unlimited” number of antennas to a practical technology that has been demonstrated in field trials, as described in Harris et al. (2017) and Malkowsky et al. (2017) among others and included as one of the main features of the 5G New Radio; see Parkvall et al. (2017).

Exact definitions of “Massive MIMO” differ slightly among different researchers, but the underlying idea is always to equip base stations with arrays of many electronically steerable antennas. These antennas serve many users simultaneously, in the same time-frequency resource. A minimum of 64 base station antennas is commonly considered, and the goal is to support spatial multiplexing of tens of users, each equipped with one or multiple antennas. The very large number of antennas is a design choice to limit inter-user interference and provide a beamforming gain wherever the user is. The textbooks by Marzetta et al. (2016) and Björnson et al. (2017) advocate the use of time-division duplexing (TDD) operation, which permits exploitation of the uplink-downlink reciprocity of the radio propagation. Specifically, the base station uses channel estimates obtained from uplink pilots transmitted by the users to learn the channels in both directions. These estimates are then used for multiuser precoding in the downlink and multiuser detection in the uplink. With TDD operation, Massive MIMO is entirely scalable with respect to the number of base station antennas, in the sense that the amount of resources spent on channel estimation is independent of the number of antennas.

Less restrictive definitions of Massive MIMO are also common. While the preferred operation of Massive MIMO is in TDD mode, where reciprocity between the uplink and downlink holds, operation in frequency-division duplex (FDD) mode is possible in some cases, e.g., using the concepts provided by Adhikary et al. (2013) and Choi et al. (2014), but Flordelis et al. (2018) show that there is a significant performance penalty. While the propagation models in much Massive MIMO literature suggest sub-6 GHz operation, see e.g., Marzetta et al. (2016), Björnson et al.

(2017), and references therein variants of Massive MIMO are also considered for millimeter wave frequency bands.

Three key features of Massive MIMO are as follows:

- High spectral efficiency (measured in bits/s/Hz), primarily attributed to the spatial multiplexing gain
- Provision of uniformly good quality of service in the entire coverage area, by means of beamforming and power control
- Support for high user mobility by efficient channel acquisition (primarily in TDD operation)

The word “massive” refers to the number of antennas and not to the physical size of a base station. Since low-gain antennas are typically used, the antenna arrays can have attractive form factors, e.g., in the 2 GHz band, a half-wavelength-spaced rectangular array with 200 dual-polarized elements is on the order of 1.5×0.75 meters large. At higher carrier frequencies, the arrays will be even smaller, since the dimensions scale with the carrier wavelength. No specific array geometry is required or assumed in Massive MIMO, and distributed antenna deployments are feasible.

The massive number of antennas can give rise to two desirable propagation phenomena. The first is channel hardening, which is a form of massive spatial diversity implying that the link performance fluctuates very little over time and frequency, even when communicating over a fading channel. The second is favorable propagation, which is the ability for the base station to separate the users in the spatial domain; technically, the channel responses associated with different users become nearly orthogonal with an increasing number of antennas.

Information theory, signal processing, and power control for Massive MIMO are well understood, as demonstrated by Marzetta et al. (2016) and Björnson et al. (2017). An important insight is that the link performance over a fading channel can be rigorously quantified in terms of an effective signal-to-interference-and-noise

ratio (SINR), which depends only on the average channel properties between the users and the base stations and on certain system parameters. These expressions take into account the effects of all significant physical phenomena: small-scale and large-scale fading, fading correlation, intra- and intercell interference, channel estimation errors, and pilot interference from pilot reuse in the network (also known as pilot contamination). In the moderately large number-of-antennas regime, the closed-form capacity bounds that result from these effective SINR expressions become convenient proxies for the link performance achievable with practical coding and modulation, power control, and resource allocation schemes.

Massive MIMO is not only a groundbreaking technology for wireless communications, which can vastly increase the spectral efficiency and uniformity of the quality-of-service over previous technologies. It is also an elegant and mathematically rigorous approach to teaching of wireless communications. A comprehensive analytical understanding of the key properties that determine wireless communication link and system performance is facilitated by the capacity bound analysis of Marzetta et al. (2016). Such analyses have simply not been possible before as the corresponding information theory was too complicated for any practical use.

Key Applications

Fifth-generation (and beyond) mobile access networks; Wireless communications with autonomous vehicles; Backhauling in small-cell networks

Definitions

Beam division multiple access (BDMA) transmission refers to a wireless multiple access scheme, where a base station employs massive antennas to generate beams and communicates with several users simultaneously. Multiple access is achieved in BDMA by assigning beams to individual users, and beams for different users are orthogonal (nonoverlapping).

Historical Background

In developing next-generation wireless networks, massive multiple-input multiple-output (MIMO)

is a promising technology to deliver high spectral and power efficiencies (Rusek et al. 2013; Wang et al. 2014). In massive MIMO system, a base station (BS) employs a large number of antennas to simultaneously and jointly serve multiple mobile users. Assuming an environment of independent and identically distributed propagation MIMO channels, such a massive MIMO configuration has several attractive features (Marzetta 2010) including: (1) downlink channel vectors for different users become asymptotically orthogonal; (2) independent user beamforming can mitigate intra-cell interferences and uncorrelated noises; and (3) transmit power can be asymptotically low.

The aforementioned benefits of massive MIMO depend heavily on the availability of channel state information at the transmitter (CSIT). In practice, the CSIT availability hinges on time-division duplex (TDD) operation through uplink training and the channel reciprocity assumption. Yet, training overhead scales linearly with the total number of user antennas. When the number of users is large or when each user has multiple antennas, the overhead becomes prohibitively high. In addition, as user mobility increases, channel coherence time becomes relatively short. As a result, it becomes much more difficult to obtain accurate instantaneous CSIT for medium- or high-mobility user applications. Although the propagation channel itself is likely reciprocal in TDD, the uplink/downlink RF hardware chains at both BS and mobile transceivers are often not reciprocal (Choi et al. 2014). These practical limitations pose serious challenges to accurate CSIT acquisition in TDD systems, especially when dealing with high user mobility. For frequency-division duplex (FDD) systems without instantaneous channel reciprocity, the required number of independent pilot symbols for CSIT acquisition scales with the number of BS antennas, as does the CSIT feedback overhead (Jindal 2006). Therefore, it is likely to be more difficult to acquire global real-time CSIT for precoding in FDD.

Instantaneous CSIT acquisition represents a significant bottleneck; it is more desirable to exploit statistical CSIT for massive MIMO

systems. Statistical CSI varies over much larger time scales than instantaneous channel parameters. Moreover, the uplink and downlink statistics are usually reciprocal in both FDD and TDD systems (Barriac and Madhow 2004). Therefore, the statistical channel information can be more easily obtained by exploiting reciprocity, even for terminals equipped with multiple antennas.

Beam division multiple access (BDMA) transmission scheme is an effective technology (Sun et al. 2015), which can approach optimal transmission, when only statistical CSIT is available at the BS. In the beam domain, different beams transmit independent signals, and one beam transmits signal to at most one user. The BDMA transmission consists of the following steps: (1) acquiring channel statistics, (2) scheduling users and beams, (3) transmitting pilot and data in the uplink and downlink. By user and beam scheduling, beams assigned to different users are nonoverlapping (orthogonal). Thus, BDMA transmission decomposes massive MU-MIMO channel links to multiple small-scale SU-MIMO interference channel links. For each link, the number of transmit beams is much smaller than the number of antennas, and the channel state information between beams and users can be obtained via channel training. BDMA transmission can cope with the difficulties of instantaneous CSIT acquisition, reduce the inter-user interference, and increase the spectrum efficiency. Moreover, BDMA transmission can reduce the complexity of transceiver design and can be applied in TDD or FDD systems.

Beam Domain Channel

A single-cell system consists of one BS equipped with M antennas, and K users, each with N antennas, randomly distributed in the cell. For a physical channel model, suppose that there are P physical paths between the BS and users, and the p th path of the k th user has an attenuation of $a_{p,k}$, an angle $\varphi_{p,k}$ with the transmit antenna array, and an angle $\theta_{p,k}$ with the receive antenna array. For a wideband channel, after OFDM operation, the channel frequency response matrix in the ℓ th

subcarrier of the k th user is given by (Tse and Viswanath 2005):

$$\mathbf{H}_{k,\ell}^d = \sum_{p=1}^P a_{p,k} e^{-j2\pi d_{p,k}/\lambda_c} \mathbf{e}_r(\theta_{p,k}) \mathbf{e}_t^H(\varphi_{p,k}) e^{-j2\pi \ell \tau_{p,k}}, \quad (1)$$

where the superscript d means downlink, $d_{p,k}$ is the physical distance between transmit antenna 1 and receive antenna 1 along path p , λ_c is the carrier wavelength, and $\tau_{p,k}$ is the propagation delay associated with the p th path. Moreover, $\mathbf{e}_r(\theta) \in \mathbb{C}^{N \times 1}$ satisfying $\|\mathbf{e}_r(\theta)\|_2 = 1$ is the user antenna array response vector corresponding to the angle of arrival (AoA) θ , and $\mathbf{e}_t(\varphi) \in \mathbb{C}^{M \times 1}$ satisfying $\|\mathbf{e}_t(\varphi)\|_2 = 1$ is the BS antenna array response vector corresponding to the angle of departure (AoD) φ .

Assume that the array response vectors corresponding to distinct AoDs are asymptotically orthogonal with infinite number of antennas at the BS (You et al. 2015), i.e.:

$$\lim_{M \rightarrow \infty} \mathbf{e}_t^H(\varphi) \mathbf{e}_t(\eta) = \delta(\varphi - \eta). \quad (2)$$

At the user side, the angle $\theta_{n,k}$ is the sampling of receive signals. When the response vectors are orthogonal, i.e.:

$$\mathbf{e}_r^H(\theta_{n,k}) \mathbf{e}_r(\theta_{n',k}) = \delta(n - n'), \quad (3)$$

users can separate these orthogonal direction signals perfectly. For uniform linear antenna arrays, uniform sampling of $\sin(\theta_{n,k})$, i.e., $\sin(\theta_{n,k}) = n/N$, is a classical choice for spatial angles (Sayeed 2002).

The channel matrix in (1) can be rewritten as

$$\begin{aligned} \mathbf{H}_{k,\ell}^d &= \sum_{n=1}^N \sum_{m=1}^M \left[\tilde{\mathbf{H}}_{k,\ell}^d \right]_{nm} \mathbf{e}_r(\theta_{n,k}) \mathbf{e}_t^H(\varphi_m) \\ &= \mathbf{U}_k \tilde{\mathbf{H}}_{k,\ell}^d \mathbf{V}^H \end{aligned} \quad (4)$$

where $\mathbf{U}_k = [\mathbf{e}_r(\theta_{1,k}), \mathbf{e}_r(\theta_{2,k}), \dots, \mathbf{e}_r(\theta_{N,k})] \in \mathbb{C}^{N \times N}$ is a unitary matrix and $\mathbf{V} = [\mathbf{e}_t(\varphi_1), \mathbf{e}_t(\varphi_2), \dots, \mathbf{e}_t(\varphi_M)] \in \mathbb{C}^{M \times M}$. As the

number of BS antennas M tends to infinity, $\mathbf{V}$ becomes an asymptotically unitary matrix. We call $\tilde{\mathbf{H}}_{k,\ell}^d$ the *beam domain channel matrix* with one direction of AoD called a beam. Following Sayeed (2002), we have the following sampling approximation:

$$\left[\tilde{\mathbf{H}}_{k,\ell}^d\right]_{nm} \approx \sum_{p \in S_{r,n} \cap S_{t,m}} a_{p,k} e^{-j2\pi d_{p,k}/\lambda_c} e^{-j2\pi \ell \tau_{p,k}} \quad (5)$$

where $S_{r,n}$ is the set of all paths whose receive angles are nearest to the angle $\theta_{n,k}$ and $S_{t,m}$ is the set of paths whose transmit angle is exactly equal to the angle φ_m . In the beam domain, different elements of the channel matrix represent the signals of different transmit and receive angles. Different from the summation of all path signals in the physical domain, the beam domain channel can separate the paths of different angles by different beams.

Define the eigenmode channel coupling matrix as (Gao et al. 2009)

$$\boldsymbol{\Omega}_{k,\ell}^d = \mathbb{E} \left\{ \tilde{\mathbf{H}}_{k,\ell}^d \odot (\tilde{\mathbf{H}}_{k,\ell}^d)^* \right\} \quad (6)$$

whose elements specify the mean amount of energy that is coupled from the m th eigenvector of the BS to the n th eigenvector of users. The eigenmode channel coupling matrix $\boldsymbol{\Omega}_{k,\ell}^d$ is likewise independent of subcarriers. Then, when the BS has access only to the channel coupling matrix, the optimal transmit strategies are the same for all subcarriers, and the subscript ℓ can be omitted. This observation will significantly decrease the overhead of CSIT acquisition.

Beam Division Multiple Access Transmission

As the channel gains of different paths are independent, the beam domain channel matrix $\tilde{\mathbf{H}}_k^d$ (whose subscript ℓ is omitted) has uncorrelated elements. The optimal transmission in the beam domain is that BS transmits independent signals

through different beams and that different set of beams transmit signals to different users, which is called beam division multiple access (BDMA) transmission (Sun et al. 2015, 2017; You et al. 2017). In the BDMA transmission, the beams for different users are nonoverlapping (orthogonal), and one beam transmits at most one user's signal.

Figure 1 illustrates the BDMA downlink and uplink transmission. In BDMA downlink transmission, as shown in Fig. 1a, BS employs different beam sets transmitting different user's signal, and the received signal at user k is

$$\begin{aligned} \mathbf{y}_k^d &= [\tilde{\mathbf{H}}_k^d]^{\mathcal{B}_k} \tilde{\mathbf{x}}_k + \sum_{k' \neq k} [\tilde{\mathbf{H}}_k^d]^{\mathcal{B}_{k'}} \tilde{\mathbf{x}}_{k'} + \mathbf{n}_k \\ &= [\tilde{\mathbf{H}}_k^d]^{\mathcal{B}_k} \tilde{\mathbf{x}}_k + \mathbf{n}_k^d, \end{aligned} \quad (7)$$

where $\mathcal{B}_k$ is the beam set for user k , $\tilde{\mathbf{x}}_k = \mathbf{V}^H \mathbf{x}_k$ is the beam domain transmitted signal, and $\mathbf{n}_k^d$ is the aggregate interference plus noise.

In BDMA uplink transmission, as shown in Fig. 1b, BS employs beam set $\mathcal{B}_k$ to receive signal of user k , and the received signal of user k at the BS is

$$\begin{aligned} \mathbf{y}_k^u &= [\tilde{\mathbf{H}}_k^u]^{\mathcal{B}_k} \tilde{\mathbf{x}}_k + \sum_{k' \neq k} [\tilde{\mathbf{H}}_k^u]^{\mathcal{B}_{k'}} \tilde{\mathbf{x}}_{k'} + \mathbf{n} \\ &= [\tilde{\mathbf{H}}_k^u]^{\mathcal{B}_k} \tilde{\mathbf{x}}_k + \mathbf{n}_k^u, \end{aligned} \quad (8)$$

where the superscript u means uplink and $\mathbf{n}_k^u$ is the aggregate interference plus noise of user k in the uplink.

BDMA transmission scheme for MU-MIMO in the beam domain is illustrate in Fig. 2, which consists of the following key components:

1. The BS acquires channel coupling matrices from all users in its own cell. The channel coupling matrices acquisition consists of two steps: first in the uplink, different users transmit sounding signals. Secondly, the BS estimates the instantaneous CSI to calculate channel coupling matrices. Since the statistical CSI varies much slower than the instantaneous CSI, we do not need to estimate the whole channel realizations, and therefore, the

Massive MIMO BDMA Transmission, Fig. 1 (a) BDMA downlink transmission and (b) BDMA uplink transmission

Massive MIMO BDMA Transmission, Fig. 2 Block diagram of a BDMA transmission scheme

overhead of statistical CSI is much less than that of instantaneous CSI.

2. The BS schedules users to be sufficiently separated in beam domain. Based on the channel coupling matrices, the user scheduler selects users for maximizing the sum-rate with the constraints that different user beams are nonoverlapping. After user scheduling, beams at the BS are divided into different sets, leading to decomposing the massive MU-MIMO link into small dimensional SU-MIMO links.
3. Uplink and downlink transmissions consist of pilot training and data transmission. In the training step, since users are separated by different beam sets at the BS, uplink and downlink pilot sequences do not need to be orthogonal. According to the number of selected users, optimal pilot sequences are designed to minimize the channel estimation error. The

receivers in the uplink and downlink estimate the reduced dimensional channel matrices, as well as the aggregate interference covariance matrix for data detection. With channel information, the receivers utilize the iterative soft-input and soft-output (SISO) detection and SISO decoding.

The BDMA scheme is suitable for FDD systems with only statistical CSI at the BS. Note, however, that the approach also applies to TDD systems, when instantaneous CSI at the BS is not available, e.g., for cases involving high user mobility.

Conclusion

BDMA transmission is a multiple access scheme in massive MIMO communication systems. In

the beam domain, the elements of the channel matrix represent the channels between different transmit and receive angles. According to the channel statistics, BS assigns nonoverlapping beams to different users, and users are separated by different beams. Massive MU-MIMO transmission link is decomposed into multiple small dimensional SU-MIMO links, to cope with the difficulties of instantaneous CSIT acquisition and reduce the complexity of transceiver design.

Key Applications

BDMA transmission is an optimal and effective multi-user transmission scheme, when only statistical CSIT is available in both TDD and FDD systems. Employing massive antennas at the BS, BDMA transmission explores the spatial resource and provides high spatial resolution by different beams. BDMA transmission helps to provide high spectral efficiency and reduce the complexity of transceiver design.

Definitions

Massive MIMO channel estimation is a procedure to obtain channel state information (CSI) under systems consisting of large-scale multiple antennas at both transmitter and receiver before detecting the transmitted data. CSI refers to the transmission matrix between the transmitter and receiver, which includes scattering, fading, and power decay effects of a communication link. Massive MIMO channel estimation performance determines the suitability of massive MIMO techniques, offers the possibility of improving link reliability and network capacity, and reduces latency and interference.

Historical Background

Massive MIMO technology has been widely studied and incorporated into many standards, such as long-term evolution (LTE) and IEEE802.11 (Wi-Fi), because it can significantly improve the capacity and reliability of wireless systems Larsson et al. (2014).

Over the past two decades, the speed of wireless networks has improved, starting from SISO in 2000, to SU-MIMO in 2009, and to MU-MIMO in 2012. In the near future, around 2020, massive MIMO aims to achieve a data rate of more than 10 Gbps Andrews et al. (2014). Massive MIMO is a bold vision of development from classical MIMO by using very large-scale antennas at both ends, which are fully coherent and adaptive. Wireless channel diversity is applied to provide links with higher speed and reliability.

The larger the number of antennas placed at both transmitter and receiver, the more terminals can be served by the increasing data streams. This condition is expected to bring significant improvements in throughput. Furthermore, transmitters can easily avoid transmission into undesired directions, thereby alleviating harmful interference. This condition can enhance the interference cancelation and system reliability through spatial diversity Björnson et al. (2016).

The aforementioned advantages and improvements in the massive MIMO technology are based on perfect knowledge of the channel matrix, which has to be estimated. However, the massive MIMO channel estimation faces serious challenges. First, the wireless channel for massive MIMO is highly complicated, being characterized by selectivities in frequency, time, and space Lu et al. (2014). Second, the channel information is acquired by probing finite-length pilot sequences into the wireless channel because with the existence of intercell interference, the reused pilot sequences from neighboring cells would contaminate one another. According to Marzetta T.L. (2010), pilot contamination does not vanish with an unlimited number of antennas. Moreover, the training and feedback overhead become overwhelming with the increase in the number of antennas. These problems emphasize the need for alternative channel estimation schemes for increasingly large transceiver arrays.

The development pathway of the massive MIMO channel estimation should highlight the following popular techniques: To deal with the pilot contamination, Yin et al. (2013) present a novel approach that enables low-rate coordination between cells during the channel estimation phase. This approach can offer a powerful method of discriminating across mutual interfering users with strongly correlated pilot sequences. Furthermore, Yang et al. (2014) propose a new two-way training scheme for discriminatory channel estimation (DCE) by exploiting a whitening-rotation-based semi-blind method, which achieves better DCE performance than the existing DCE schemes based on linear minimum mean square error (LMMSE) channel estimator; this proposed method is robust against pilot contamination attacks. In particular, Wen et al. (2015a) introduce the estimation not only of the channel parameters of the desired links in a target cell but also those of the interference links from adjacent cells. This channel estimation method is based on sparse Bayesian learning methods and utilizes the approximately sparse property of the beamspace channel. In addition, a subspace method for channel estimation, which considers a highly sensible finite-dimensional physical

channel model, has been proposed to address the pilot contamination effect Teeti et al. (2015).

Extensive research has been conducted to exploit compressive sensing (CS) techniques to reduce the training overhead and feedback cost, especially for FDD massive MIMO systems. In Rao et al. (2014), a distributed compressive channel state information at transmitter (CSIT) estimation scheme is presented by exploiting the hidden joint sparsity structure in the user channel matrices. Additionally, a discrete Fourier transform (DFT)-aided spatial basis expansion model is introduced by Xie et al. (2016) to represent the channel, which can be applied to TDD and FDD systems under certain conditions. However, the DFT-based methods are only applicable to uniform linear arrays and have power leakage problems. Subsequently, Dai et al. (2018) design an off-grid model for downlink channel sparse representation with arbitrary 2D-array antenna geometry and apply an efficient sparse Bayesian learning (SBL) approach for sparse channel recovery and off-grid refinement. Also, CS-based massive MIMO channel estimation, such as structured compressive sensing-based spatiotemporal joint channel estimation scheme Gao et al. (2016) and beam-blocked compressive channel estimation scheme Huang et al. (2017), has been effective in reducing the required pilot overhead.

Computational complexity is one of the main challenges for massive MIMO systems. To reduce the computational complexity of the channel estimation, a set of low-complexity Bayesian channel estimators, called polynomial expansion channel estimators, are demonstrated by Shariati et al. (2014). To further reduce the computational complexity and improve the accuracy of channel estimation, Wen et al. (2015b) adopt a joint channel-and-data estimation method based on Bayes optimal inference.

Furthermore, other concepts, such as beam-domain channel estimation Duly et al. (2014); Xiong et al. (2017), eigenvalue-decomposition-based channel estimation Xu et al. (2017), and blind channel estimation Ngo et al. (2015), have also received considerable attention.

Foundations

Massive MIMO channel estimation methods are usually divided into two categories Hassan et al. (2017):

- *Training-based channel estimation*, which transmits known training symbols (also called pilots) at predetermined times and frequencies known by the receiver. Then, the receiver uses the known information to obtain the CSI (including the gain and phase rotation imparted by the channel at each point in time and frequency) based on the characteristics of the received training symbols.
- *Blind-based channel estimation*, which estimates the channel without the assistance of known training symbols. This method can save timefrequency resources and offer higher bandwidth efficiency. As the blind-based channel estimation method has lower speed and poorer performance than the training-based method, researchers pay closer attention to the latter. Thus, the later part of this section considers only the training-based channel estimation methods.

Two common modes for massive MIMO systems exist, namely, time division duplexing (TDD) and frequency division duplexing (FDD) Lu et al. (2014). In FDD-mode massive MIMO systems, the uplink and downlink use different frequency bands. Therefore, the uplink and downlink CSI is different. The uplink channel estimation is conducted at the base station (BS) by enabling all users to send different pilot sequences. The downlink channel estimation is followed by two steps: the BS sends pilot sequences to all users, and then the users feed the estimated downlink CSI back to the BS. As the number of antennas increases, the consumption of time resource required to transmit pilot sequences also increases in the FDD mode, whereas the TDD mode is more efficient in this aspect. In TDD systems, based on the assumption of channel reciprocity, only the uplink channel estimation is needed. According to this protocol,

the BS estimates CSI by using the pilot sequences sent by all users to estimate CSI, and then the BS uses the estimated CSI to detect the uplink data and generate beamforming vectors for downlink data transmission. The time required to transmit pilot sequences is less in the TDD mode than in the FDD mode; thus, the TDD mode is usually assumed in the study.

Pilot design is one of the key steps in massive MIMO channel estimation. Pilot placement has to comply with the following principles: the time interval between pilot symbols should be less than the coherence time of the channel and the frequency spacing should be less than the coherence bandwidth Hampton (2013). These conditions mean that in a fast-fading environment, pilots have to be placed relatively often in time, and in a highly frequency-selective channel, pilots have to be placed close together in the frequency dimension. Furthermore, based on meeting the aforementioned principles, pilots should be spaced as far apart as possible to reduce the training overhead. In massive MIMO systems, the received signal at each antenna is the superposition of the signals from all of the transmission antennas. Thus, the pilot sequences have to maintain temporal, frequency, or signal orthogonality to avoid interfering with one another. A common pilot placement strategy is packet-based in which synchronization and pilot sequences are placed in the header of the packet and then the body of the packet contains the data. Based on the hypothesis that the channel only changes slightly in the duration of a packet, the receiver can estimate the channel at the beginning of a packet and then use that estimation during the body of the packet to detect data.

Massive MIMO channel estimation techniques can be elaborated in terms of sub-6 GHz and millimeter wave (mmWave). The foundational channel estimation techniques for sub-6 GHz are introduced as follows:

- *Narrowband MIMO channel estimation:* For the quasi-static fading channel, where the packet length is shorter than the coherence time, the channel is assumed to be changeless

over one packet. Therefore, the transmitter can transmit an N_t -symbol packet, including N_p pilots, every T_{coh} seconds. Then, the receiver can estimate the channel through pilots and use the estimated channel to detect the data in the same packet. The received data are given by

$$\mathbf{Y} = \mathbf{H}\mathbf{X} + \mathbf{N}, \quad (1)$$

where $\mathbf{H}$ is the $N_r \times N_t$ channel matrix, $\mathbf{X}$ is the $N_t \times p$ pilot matrix, and $\mathbf{N}$ is the $N_r \times p$ noise matrix. The commonly used estimation techniques are the following:

- **Maximum likelihood (ML)** channel estimation aims to maximize the likelihood function of $\mathbf{H}$, namely, $\hat{\mathbf{H}}_{ML} \triangleq \arg \max_{\{\mathbf{H}\}} p(\mathbf{Y}|\mathbf{H})$. Then, after simplification, the solution of $\hat{\mathbf{H}}_{ML}$ is given by $\hat{\mathbf{H}}_{ML} = (\mathbf{Y}\mathbf{X}^H)(\mathbf{X}\mathbf{X}^H)^{-1}$.
- **Least-square (LS)** channel estimation minimizes the squared error between the actual received signal $\mathbf{Y}$ and the estimated received signal $\hat{\mathbf{Y}} = \hat{\mathbf{H}}\mathbf{X}$, that is, $\hat{\mathbf{H}}_{LS} \triangleq \arg \min_{\{\hat{\mathbf{H}}\}} \|\mathbf{Y} - \hat{\mathbf{Y}}\|_F^2$. Then, after simplification, the solution of $\hat{\mathbf{H}}_{LS}$ is expressed by $\hat{\mathbf{H}}_{LS} = (\mathbf{Y}\mathbf{X}^H)(\mathbf{X}\mathbf{X}^H)^{-1}$, which is equivalent to the ML channel estimation.
- **Linear minimum mean square error (LMMSE)** channel estimation minimizes the mean square error between the actual and estimated channels; this error is expressed as $\hat{\mathbf{H}}_{LMMSE} \triangleq \arg \min_{\{\hat{\mathbf{H}}\}} \mathbb{E} \left\{ \|\mathbf{H} - \hat{\mathbf{H}}\|_F^2 \right\}$. After simplification, the solution of $\hat{\mathbf{H}}_{LMMSE}$ is given by $\hat{\mathbf{H}}_{LMMSE} = \mathbf{Y}(\mathbf{I} + \mathbf{X}^H\mathbf{X})^{-1}\mathbf{X}^H$.
- **Maximum a posteriori (MAP)** channel estimation is designed to maximize the posterior probability distribution function, that is, $\hat{\mathbf{H}}_{MAP} \triangleq \arg \max_{\{\mathbf{H}\}} p(\mathbf{H}|\mathbf{Y})$.

The ML and LS channel estimations are unbiased estimation techniques as long as the

noise has a zero-mean symmetrical distribution. The LMMSE channel estimation is not unbiased, whereas with the increase in signal-to-noise ratio, it becomes unbiased and is equivalent to the ML/LS estimation.

- *Broadband MIMO channel estimation:* When the bandwidth of the signal is greater than the channel coherence bandwidth, the frequency-selective fading channel occurs. The orthogonal frequency division multiplexing (OFDM) technique is commonly used in broadband massive MIMO applications. In OFDM systems, the pilot is placed in both time and frequency domains, and the frequency domain channel is usually estimated by ML/LS/LMMSE channel estimation techniques.
- *CS-based mmWave massive MIMO channel estimation:* CS techniques bring numerous benefits to mmWave massive MIMO beamspace channel estimation, by using CS channel estimation algorithms. The system operation requires a relatively small training overhead. To adapt to various channel estimation scenarios, several CS algorithms have been introduced, such as LASSO Tibshirani (1996), orthogonal matching pursuit Cai et al. (2011), support detection Gao et al. (2017), and sparse non-informative parameter estimator-based cospase analysis approximate message passing for imaging Yang et al. (2018) channel estimation algorithms.

Finally, the bit error ratio and normalized mean square error are commonly used to study the performance of massive MIMO channel estimation techniques.

Key Applications

Massive MIMO channel estimation is involved in most wireless communication systems, especially in 5G mobile communications.

Synonyms

Cooperative spectrum sharing; Dynamic spectrum access; Two-sided matching

Definition

Dynamic spectrum access, also known as opportunistic spectrum access, is a new spectrum access paradigm, which allows unlicensed secondary users (SUs) to access the licensed spectrum of primary users (PUs) in an opportunistic way, and hence can effectively increase the spectrum efficiency and alleviate the spectrum scarcity. *Cooperative spectrum sharing* is an effective form of dynamic spectrum access, where SUs relay the transmissions of PUs in exchange for the opportunity of accessing the licensed spectrum of PUs, and thus, it can offer the necessary incentives for both PUs and SUs in dynamic spectrum access. *Two-sided matching*, or matching, is an efficient framework for analyzing the inter-dependent interactions between two disjoint player sets such as PUs and SUs in cooperative spectrum sharing.

Massive Multiuser MIMO

► [Massive MIMO](#)

Historical Background

Nowadays, wireless spectrum is becoming increasingly congested and scarce with the

explosive development of wireless devices and services. Dynamic spectrum access (DSA) is a promising approach to increase the spectrum efficiency and alleviate the spectrum scarcity, by allowing unlicensed secondary users (SUs) to opportunistically access the spectrum licensed to primary users (PUs) (Zhao and Sadler 2007; Akyildiz et al. 2008). Hence, it has become one of the important information and communication technologies (ICT) for future wireless networks. To successfully implement DSA in practice, it is important to offer necessary incentives for PUs to open their spectrum for SUs' utilizations and for SUs to access the PUs' spectrum despite the potential costs (Niyato and Hossain 2008; Gao et al. 2011a, b, 2013; Huang et al. 2006; Huang 2013; Luo et al. 2015).

Cooperative spectrum sharing (CSS) has been recently proposed as an effective approach to offer necessary incentives for both PUs and SUs in DSA (Simeone et al. 2008; Zhang and Zhang 2009; Wang et al. 2010; Duan et al. 2011, 2014). The key idea is to enable SUs to act as relay and help the transmission of PUs in exchange for the opportunities of accessing the PUs' licensed spectrum. In such a way, PUs can increase the transmission efficiency with the help of SUs (and hence can save some spectrum resource for SUs), and SUs can obtain the desired transmission opportunity on the PUs' licensed spectrum (at the cost of consuming energy resource to help PUs). Thus, it will lead to a win-win situation for PUs and SUs.

Existing work on CSS mainly focused on the interactions between *one* PU and one or multiple SUs (Simeone et al. 2008; Zhang and Zhang 2009; Wang et al. 2010; Duan et al. 2011, 2014). The PU, as the monopolist, can dominate the cooperation process. Some works assumed that the PU has complete information of SUs and formulated the problem into Stackelberg games (Simeone et al. 2008; Zhang and Zhang 2009; Wang et al. 2010), while others considered that the PU has limited information about SUs and introduced auction theory and contract theory to elicit the private information of SUs (Duan et al. 2011, 2014). However, these models and approaches are difficult to be extended to the sce-

nario of multiple PUs and multiple SUs, which is more general and practical.

This entry focuses on discussing the general CSS model with multiple PUs and SUs. Although the multi-PU multi-SU scenario is more general and practical, it is also much more challenging to analyze the interactions between multiple PUs and multiple SUs, as not only SUs compete with each other for the PUs' licensed spectrums, but PUs also compete with each other for the SUs' collaborations.

Foundations

In a multi-PU multi-SU model, the first key challenging problem is to decide *which PU cooperates with which SU*. Note that multiple SUs may be interested in cooperating with the same PU, and so are PUs. Thus, competition inherently exists not only among PUs but also among SUs. This is a typical *two-sided matching* problem (Gale and Shapley 1962). The second challenging problem is to decide *how each pair of matched PU and SU cooperate with each other*. That is, how much spectrum resource that the PU would like to share with the SU, and how much effort (e.g., energy) that the SU would like to put to help the PU. In this sense, the PU contributes spectrum resource in exchange for the SU's energy resource, or equivalently, the SU contributes energy resource in exchange for the PU's spectrum resource. Thus, this can also be viewed as *resource exchange* between them.

Combining the above two problems, the interaction between multiple PUs and SUs can be formulated as an extended two-sided matching problem with varying resource exchange. In this section, the general CSS model, the extended two-sided matching formulation, and the conditions for stable matching outcome (equilibrium) will be discussed in detail.

General CSS Model

A general CSS model consists of multiple PUs and multiple SUs. Let $\mathcal{M} \triangleq \{1, \dots, M\}$ denote the set of PUs and $\mathcal{N} \triangleq \{1, \dots, N\}$ denote the set of SUs. Each PU owns a dedicated licensed

spectrum band, and the spectrum bands of different PUs are *nonoverlapping* (i.e., orthogonal). Thus, there is no interference on different PUs' spectrum bands. Each SU is equipped with one radio frequency module and hence can access one PU's spectrum band at a particular time.

By cooperative spectrum sharing, SUs act as relays to help the transmissions of PUs in exchange for accessing the PUs' spectrum bands. Assume that each PU can employ *only one* SU as cooperative relay and each SU can help *only one* PU at a particular time. Note that in practice, a PU can possibly employ multiple SUs as cooperative relays. However, existing study Yi et al. (2010) has shown that choosing one relay (i.e., the most appropriate one) is usually sufficient to achieve all or almost all cooperative gain. Similarly, in practice, an SU can possibly help multiple PUs by using a proper multiple access technique. From the economic perspective, however, there is no incentive for an SU to help multiple PUs, as he can only access one PU's frequency band at a particular time.

With the above assumption, the assignment between PUs and SUs is essentially a *one-to-one matching* between them, where one PU (or SU) can only be matched with one SU (or PU). Let μ_n denote the PU matched with SU n and μ_m denote the SU matched with PU m . Note that $\mu_n = \emptyset$ or $\mu_m = \emptyset$ denotes that SU n or PU m is not matched with any PU or SU. Clearly, $\mu_n = m$ if and only if $\mu_m = n$.

For a pair of matched PU and SU, their cooperation frame is divided into 2 phases: in Phase I, the PU transmits his own data with the cooperative relay of the SU; in Phase II, the SU transmits his data on the PU's frequency band (and the PU stops his own data transmission). The cooperative relay in Phase I can use any cooperative protocol such as amplified-and-forward (AF) and decode-and-forward (DF). Obviously, the cooperative gain for the PU greatly depends on the relay effort of the SU, e.g., the SU's transmission power for relaying. Moreover, the cooperative gain for the SU depends on the length of the spectrum access time (Phase II) shared by the PU. As discussed before, such a cooperation process can be viewed as *resource exchange* between them,

where the SU contributes his energy resource (in Phase I) in exchange for using the PU's spectrum resource (in Phase II).

Clearly, a larger relay effort of the SU can bring more benefit for the PU but will also incur higher cost on the SU himself, as he needs to consume more resource for helping the PU. Similarly, a larger spectrum access time shared by the PU in Phase II can bring more benefit for the SU but will reduce the PU's benefit due to the reduced time for his own transmission in Phase I. Thus, for a pair of matched PU and SU, increasing the benefit for one user will accordingly reduce the benefit for the other user. This process can be viewed as the *division of cooperative gain* between them. Let $f_n^m(x)$ denote the *gain division function* (GDF) between PU m and SU n , which characterizes the maximum gain that a PU m can achieve when cooperating with SU n and meanwhile leaving a gain of x for SU n . Let $g_n^m(y)$ denote the *inverse gain division function* (IGDF) between PU m and SU n , which characterizes the maximum gain that an SU n can achieve when cooperating with PU m and meanwhile leaving a gain of y for PU m . Obviously, IGDF is the inverse function of GDF, i.e., $y = f_n^m(x)$ if and only if $x = g_n^m(y)$.

Note that the GDF or IGDF in this entry is quite general and can be arbitrary decreasing function. An explicit example of GDF is provided in Gao et al. (2017), which is defined as the maximum data rate that PU m can achieve by jointly optimizing the SU's relay power in Phase I and spectrum access time in Phase II.

Matching Formulation

Based on the above discussion, the interactions between PUs and SUs can be formulated as an extended *two-sided matching problem*, with PUs on one side and SUs on the other side. A PU is matched with an SU (or equivalently, an SU is matched with a PU) means that the PU cooperates with the SU under certain cooperative gain division (or resource exchange) agreement between them. Accordingly, a *matching outcome* defines not only the cooperative relationships of all PUs and SUs (i.e., who cooperates with whom), but also the cooperative gain division

(or resource exchange) between each pair of matched PU and SU (i.e., how they cooperate with each other). Formally, such a matching outcome can be expressed as

$$\{(\mu_n, \delta_n), \forall n \in \mathcal{N}\}, \quad (1)$$

where (μ_n, δ_n) denotes the matching result for each SU $n \in \mathcal{N}$, with μ_n denoting his matched PU and δ_n denoting his achieved cooperative gain. Obviously, in such a matching outcome, the (maximum) cooperative gain that PU μ_n can achieve is $f_n^{\mu_n}(\delta_n)$. Note that if SU n is not matched with any PU, i.e., $\mu_n = \emptyset$, he cannot achieve any cooperative gain, i.e., $\delta_n = 0$.

Note that a matching outcome may not be stable, as some users may discard their matched partners or change the gain division (resource exchange) agreement with their partners. For example, a matching outcome is not stable, if there exist a PU and an SU who are not matched with each other, but both prefer to be (i.e., both can increase their gains by matching with each other). In such a case, they would match with each other by discarding their respective partners. On the other hand, a matching outcome is also not stable, if there exist a PU and an SU who are matched with each other, but one or both prefer not to be (i.e., one can increase his gain by not matching with the other). In such a case, the user would discard his partner and match with another user or remain single.

Therefore, a natural question arising in such an extended two-sided matching problem is *what are the stable matching outcomes, from which none of PUs and SUs has the incentive to deviate*. A stable matching outcome is often referred to as an *equilibrium* of the matching. Formally,

Definition 1 (Equilibrium) An equilibrium of a matching is a stable matching outcome, where no user can improve his benefit via the unilateral deviation (i.e., choosing another partner or changing the gain division in agreement with his partner).

In the next section, the necessary and sufficient conditions for stable matching outcome (equilibrium) will be derived systematically.

Stable Matching Outcome (Equilibrium)

Suppose $\{(\mu_n, \delta_n), \forall n \in \mathcal{N}\}$ is an equilibrium. Then, for each pair of matched SU and PU (say, SU n and PU μ_n), the following conditions must hold: (i) both SU n and PU μ_n have no incentive to break the current matching, by pairing with another user or remaining single, and (ii) all PUs other than μ_n (or all SUs other than n) have no incentives to discard their respective partners and pair with SU n (or PU μ_n). This leads to the following necessary conditions for equilibrium.

Lemma 1 (Necessary Conditions)

If $\{(\mu_n, \delta_n), \forall n \in \mathcal{N}\}$ is an equilibrium, then for each PU μ_n (matched with SU n), the following condition holds:

$$\begin{aligned} \text{(IR)} \quad & f_n^{\mu_n}(\delta_n) \geq 0, \\ \text{(IC)} \quad & f_n^{\mu_n}(\delta_n) \geq f_k^{\mu_n}(\delta_k), \quad \forall k \neq n, \\ \text{(CC)} \quad & f_{\mu_m}^m(\delta_{\mu_m}) \geq f_n^m(\delta_n), \quad \forall m \neq \mu_n. \end{aligned} \quad (2)$$

(where $f_n^m(x)$ is the GDF, denoting the (maximum) gain that PU m can achieve when matching with SU n and leaving a gain of x for SU n).

The first condition is called the *Individual Rationality* (IR) condition, the second condition is called the *Incentive Compatibility* (IC) condition, and the third condition is called the *Competitive Compatibility* (CC) condition. The IC and IR conditions ensure that each PU μ_n (matched with SU n) has no incentive to discard his current partner SU n by remaining single or matching with another SU. The CC condition ensures that all PUs other than μ_n have no incentive to discard their current partners and compete with PU μ_n for SU n .

The IR, IC, and CC conditions lead to the following constraints on δ_n :

$$\begin{aligned} \text{(IR)} \quad & \Rightarrow \delta_n \leq g_n^{\mu_n}(0), \\ \text{(IC)} \quad & \Rightarrow \delta_n \leq \min_{k \neq n} \{g_n^{\mu_n}(f_k^{\mu_n}(\delta_k))\}, \\ \text{(CC)} \quad & \Rightarrow \delta_n \geq \max_{m \neq \mu_n} \{g_n^m(f_{\mu_m}^m(\delta_{\mu_m}))\}, \end{aligned} \quad (3)$$

where $g_n^m(x) = f_n^{\mu_n(-1)}(x)$ denotes maximum gain that SU n can achieve when matching with PU m and leaving a gain of x for PU m . The above

constraints on δ_n further lead to the following upper-bound and lower-bound for each δ_n :

$$\bar{\delta}_n \triangleq \min_{k \neq n} \{g_n^{\mu_n}(f_k^{\mu_n}(\delta_k)), g_n^{\mu_n}(0)\}. \quad (4)$$

$$\underline{\delta}_n \triangleq \max_{m \neq \mu_n} \{g_n^m(f_{\mu_n}^m(\delta_{\mu_n})), 0\}, \quad (5)$$

Intuitively, the gain for SU n , i.e., δ_n , cannot be higher than the threshold $\bar{\delta}_n$, otherwise PU μ_n (matched with SU n) would be better off by matching with another SU or remaining single. On the other hand, δ_n cannot be lower than the threshold $\underline{\delta}_n$, otherwise some other PUs $m \neq \mu_n$ (matched with other SUs) will have the incentive and ability to compete for SU n (by leaving a slightly higher gain for SU n).

With the above upper-bound and lower-bound for each δ_n , the necessary conditions in Lemma 1 can be rewritten as $\underline{\delta}_n \leq \delta_n \leq \bar{\delta}_n, \forall n \in \mathcal{N}$. It is important to note that these conditions are not only necessary, but also sufficient. Formally,

Lemma 2 (Necessary and Sufficient Conditions)

A matching outcome $\{(\mu_n, \delta_n), \forall n \in \mathcal{N}\}$ is an equilibrium, if and only if:

$$\underline{\delta}_n \leq \delta_n \leq \bar{\delta}_n, \quad \forall n \in \mathcal{N}, \quad (6)$$

where $\bar{\delta}_n$ and $\underline{\delta}_n$ are defined in Eqs. (4) and (5), respectively.

Key Applications

Two-sided matching is a widely used efficient framework for analyzing the interactions between two disjoint player sets in two-sided market scenarios. In such scenarios, the matching theory can systematically capture not only the cooperative interactions between users in different sides but also the competitive interactions between users on the same side. Most early results in this area mainly focused on the matching under complete information, without considering the incentive issues under incomplete information.

The first two-sided matching model was studied in Gale and Shapley (1962), where a basic two-sided matching model with nontransferable utilities was proposed to study the marriage market. Shapley and Shubik (1971) and Thompson (1980) studied the more general models with additive and transferable utilities. Kelso and Crawford (1982) studied the two-sided labor models with nontransferable utilities. Some later works such as Kojima and Pathak (2009) studied the incentive issue in matching under incomplete information. Gao et al. (2017) applied the matching theory to analyze the dynamic spectrum access problem between PUs and SUs in cognitive radio networks.

Open Problems

In this section, some open problems for the applications of matching to communication networks are outlined.

- *One-to-Many or Many-to-Many Matching:* This entry mainly focused on the one-to-one matching model, where a PU can only employ one SU as cooperative relay and an SU can only help one PU. In practice, however, a PU can potentially employ multiple SUs as relays and an SU can potentially help multiple PUs. This will lead to a more complicated one-to-many or many-to-many matching.
- *Implementation of Equilibrium:* This entry mainly focused on characterizing the conditions of equilibrium, without considering the implementation of equilibrium under different information scenarios, especially the incomplete information scenario. That is, what equilibrium will emerge under different information scenarios is a challenging open problem.

Matching game for load balancing in wireless cellular networks

Definitions

Load distribution in wireless cellular networks refers to assigning the mobile users (MUs) to the base stations (BSs) throughout the network. Multi-tier cellular networks (MTCNs) are a kind of wireless cellular networks where the access points come in various size, capacity,

and transmit power. Load distribution in such networks should take into account the disparity among the access points so as to optimize the network performance.

Introduction

The concept of multi-tier cellular network (MTCN) is seen as a promising technology to cope with the unprecedented proliferation in wireless data traffic by increasing the network capacity (Damjanovic et al. 2011). In MTCN, traditional macrocells coexist with other smaller cells, such as microcells and femtocells, which are the catalyst behind improving wireless networks in densely populated areas. In comparison to their macrocell counterparts, small cell transmissions range between a mere 0.25 and 6 W and extend coverage up to several hundred meters. Hence, by reducing the distance between the transmitter and the receiver, small cells provide higher data rates as well as more energy-efficient way of communication for their users. However, the deployment of MTCN comes with several new technical challenges, such as interference management, network planning, and load distribution (Ghosh et al. 2012). In particular, load distribution strategy in MTCN is of crucial importance for the overall network performance (Ye et al. 2013), as it determines which user should be served by which BS and when. In this article, we propose a novel strategy for load distribution in the downlink of MTCNs by exploiting a combination of new context information related to the users trajectory profile, their QoS demands, and the current load of each cell.

Problem Formulation

Consider the downlink of a two-tier MTCN consisting of macrocells and picocells. Let $\mathcal{M}, \mathcal{P}$, and $\mathcal{N}$ denote the set of M macro base stations (MBSs), the set of P pico base stations (PBSs), and the set of N users, respectively. For each user $n \in \mathcal{N}$, we associate a unique profile $P_n(\tau, \theta, V)$

defined by three variables τ, θ , and V representing the urgency of the service in use, the direction of its motion, and its velocity, respectively. Next, we study these parameters, and we show how such information can improve the load distribution strategy.

Service Urgency

Depending on their application in use, the users may have varying needs for the wireless resources and tolerate different amounts of latency. To capture the dependency of the users' quality of service (QoS) to the service latency, we define the users' QoS as a decreasing function of the delivery time similar to Proebster et al. (2011):

$$Q_n(t) = \frac{1}{1 + \exp(t - \tau_n)}, \quad (1)$$

where τ_n is the urgency coefficient, which accounts for the urgency of the data. The smaller is τ_n , the more urgent is the data in use.

Users' Trajectory

Users travel through the network, and active communication sessions must be transferred among the cells. To guarantee the QoS, the network should avoid risky handovers that may lead to a signal loss or erroneous communication. A handover fails when the received SINR drops under a certain threshold. To capture the effect of the users' trajectory on the user-cell association problem, we derive the probability of handover failure when a user moves between different cells.

Without loss of generality, we assume circular coverage area for tractability (Lopez-Perez et al. 2012). Consider two picocells in the vicinity of each other and assume that a user is traveling through these two cells. When a user enters a cell, the total possible time of interaction is $T_i = \frac{D}{V}$, where D is the length of coverage circle chord traversed by the user and V is its speed. Also, assume that a successful handover process needs a certain preparation time of duration T_p . If $T_i > T_p$, the user is considered as a candidate to be served; otherwise, no handover would be initiated. Note

that $D = 2R \cos(\theta)$ where R is the radius of the coverage circle and θ is the trajectory angle measured with respect to the horizontal line in the polar coordinate system. Since the directions which the user takes into the picocell are equally likely, θ is modeled as a uniform random variable $\theta \sim \text{Uniform}(-\frac{\pi}{2}, \frac{\pi}{2})$. Hence, the cumulative distribution function (CDF) of D is given by:

$$\begin{aligned} \Pr(D < d) &= 2\Pr\left(\theta > \cos^{-1}\left(\frac{d}{2R}\right)\right) \\ &= 1 - \frac{2}{\pi} \cos^{-1}\left(\frac{d}{2R}\right). \end{aligned} \quad (2)$$

We assume that for having a successful handover, the handover process must be done before the user reaches the distance $r < R$ of the picocell. When the user's path tangent to the circle with radius r around the picocell with coverage radius R , D is equal to $2\sqrt{R^2 - r^2}$. Handover fails when the user's path intersects the circle r ; thus the probability of handover failure is:

$$\begin{aligned} \Pr(D \geq 2\sqrt{R^2 - r^2}) \\ = \frac{2}{\pi} \cos^{-1}\left(\sqrt{1 - \left(\frac{r}{R}\right)^2}\right). \end{aligned} \quad (3)$$

The expression in (3) shows that the handover process becomes more reliable as r becomes smaller relative to R . The ratio of r to R varies for each cell, and thus, the different cells guarantee different levels of reliability in handover process.

User-Cell Association as a Matching Game

Matching theory is a mathematical framework for modeling the combinatorial problem of matching players in two distinct sets, depending on the individual information and preference of each player (Gu et al. 2015). Here, we model the problem of user-cell association in MTCNs as a many-to-one matching game between the cells and the users.

Definition 1 A matching μ is a function from $\mathcal{N} \cup \mathcal{P}$ to $2^{\mathcal{N} \cup \mathcal{P}}$ such that $\forall n \in \mathcal{N}$ and $\forall p \in \mathcal{P}$: (i) $\mu(n) \in \mathcal{P}$ and $|\mu(n)| \leq 1$, (ii) $\mu(p) \in 2^{\mathcal{N}}$ and $|\mu(p)| \leq q_p$ where q_p is the quota of p , and (iii) $\mu(n) = p$ if and only if n is in $\mu(p)$.

The users, who are not assigned to any member of $\mathcal{P}$, will be assigned to the nearest macro BS. Members of $\mathcal{N}$ and $\mathcal{P}$ must have strict, reflexive, and transitive preferences over the agents in the opposite set. Next, exploiting the context information about the users' trajectory and service urgency, we introduce some properly defined utility functions to effectively capture the preferences of each set.

Users' Preferences

Users demand for reliable and high-quality communication. Therefore, they prefer the SCBSs which can guarantee the safety of communication during the handover and are able to deliver the data in an acceptable time. The transmission rate a user receives from a picocell depends on the current cell load and the interference caused by the neighboring cells. Therefore, the rate of transmission is a function of current matching μ . We define the rate over load for all user-cell pairs as:

$$\begin{aligned} \nabla_{ij} &= \frac{1}{\max(1, K_j)} \\ &\log_2 \left(1 + \frac{P_j c_{ij}}{\sum_{k \neq j} P_k c_{ik} + \sigma^2} \right), \end{aligned} \quad (4)$$

where K_j is the total users being served by picocell j and P_j denotes its power. c_{ij} represents the channel coefficient between user i and picocell j . In addition, σ^2 is the power of additive noise. We define the following utility function for user i when admitted by picocell j :

$$U_i(\mu, R_j, r_j, \nabla_{ij}) = \frac{R_j}{r_j} \nabla_{ij}. \quad (5)$$

The expression in (5) shows that the users prefer lightly loaded picocells to maximize their utility. Moreover, note that this utility function could

help to offload the heavily loaded macrocells by pushing the users to more lightly loaded cells.

Picocells' Preferences

The main goal of picocells is to increase the network-wide capacity by offloading traffic from the macrocells while providing satisfactory QoS for the users. Each picocell p could serve a limited number of users, called its quota q_p . Thus, by prioritizing the users coming from congested cells, the picocells could offload the heavily loaded cells. On the one hand, each candidate user is carrying a potential utility as a function of the pervious cell p' load, i.e., $f\left(\frac{K_{p'}}{q_{p'}}\right)$. This utility depends on the current matching which determines the number of users in neighboring cells. On the other hand, picocell p would also prioritize the candidate users based on their service requirement, i.e., service urgency defined in (1). We define the following utility that picocell p obtains by serving a user n in its coverage area:

$$U_p(\mu, \tau_n, k_{p'}, q_{p'}) = \left[1 + \log \left(\frac{\max(1, k_{p'})}{q_{p'}} \right) \right] \frac{1}{\tau_n}. \quad (6)$$

The first term in (6) accounts for the offloading concept, and the second term is the utility achieved by the picocells p for its service to a specific application. Notice that the small cell p gains more utility by giving service to the users having more urgent data. Using these utility functions, users build an ordered list of the picocells based on their own preferences and vice versa. Here we define the preference relationship for the users as follows:

Definition 2 The preference relation $\succ_n$ of the user $n \in \mathcal{N}$ over the set $\mathcal{P}$ is a function that compare two picocells p and p' such that:

$$\mu \succ_n \mu' \Leftrightarrow U_n(\mu) > U_n(\mu'). \quad (7)$$

The preference relation for the picocells is defined similarly. Users and picocells rank the members of the opposite set based on the defined preference relations. Our purpose is to match the users to the small cells so that the preferences of both sides will be satisfied as much as possible; thereby the network-wide efficiency would be optimized. To solve a matching game, one suitable concept is that of a stable matching (Gu et al. 2015). A matching is said to be two-sided stable, if and only if there is no blocking pair, i.e., there is no user-picocell pair (n, p) where n prefers p to its currently matched user picocell and p prefers n to its currently matched user n .

Next, an efficient algorithm for solving the matching problem is presented, which reaches to a stable matching between users and picocells.

Proposed Algorithm

The deferred acceptance algorithm is a well-known approach to solving the standard matching games (Roth and Sotomayo 1992). However, in our game, the preferences of agents as shown in (5) and (6) depend on externalities through the entire matching, unlike classical matching problems in which preferences are static and independent of the matching. Therefore, the classical approaches such as the deferred acceptance cannot be used here because of the presence of externalities. To solve the formulated game, we propose a novel algorithm shown in Table 1.

Suppose that all the users are initially associated to the nearest macro BS. Each user sends its profile information to the neighboring picocells. Each picocell, on the other side, ranks the candidate users based on its utility and feeds back the awaiting users with its own context information including its rate over load defined in (4) and its corresponding coverage and handover circle radii R and r . Each user makes a ranking list of the available picocells and applies to the most preferred one of them. The picocells keep the most preferred ones up to their quota and reject the others. The users who have been rejected in the former phase would apply to their next

Matching Game for Load Distribution in Multi-tier Cellular Networks, Table 1

Proposed algorithm for the user-cell association game

Input: context-aware utilities and the preferences of each user

Output: Stable matching between the D2D pairs

Initializing: All the UEs are assigned to the nearest BS

Stage I: Preference Lists Composition

- Neighboring D2D users exchange their context information
- Users sort the set of acceptable candidate based on their preference functions

Stage II: Matching Evaluation

while: $\mu^{(n+1)} \neq \mu^{(n)}$

- Update the utilities based on the current matching μ
- Construct the preference lists using preference relations
- Each user n applies to its most preferred partner
- Each user accept the most preferred applicants and create a waiting list while rejecting the others

Repeat

- Each rejected user applies to its next preferred partner
- Each user update its waiting list considering the new applicants

Until: all the users assigned to a waiting list

end

M

favorite picocell, and the picocells modify their waiting list accordingly. This procedure continues until all the users are assigned to a waiting list. However, since the preferences depend on the current matching μ , an iterative approach should be employed. In each step, the utilities would be updated based on the current matching. Once the utilities are updated, the preference lists would be updated accordingly as well. Therefore, in each iteration, a new temporal matching arises, and based on this matching, the interdependent utilities are updated as well. The algorithm initiates the next iteration based on the modified preferences. The iterations run on until two subsequent temporal matchings are the same and algorithm converges. We note that the proposed algorithm will lead to a stable matching when it converges. Indeed, the deferred acceptance in stage *II* would not converge if the matching is not stable. Hence, by contradiction, whenever the algorithm converges, the matching would be stable.

Simulation Results

For our simulations, we consider a single MBS with radius 1 km and overlaid by P uniformly deployed picocells. The channels suffer from a Rayleigh fading with parameter $\sigma = 2$. Noise level is assumed to be $\sigma^2 = -121$ dBm, and the minimum acceptable SINR for the UEs is 9.56 dB. There are N users distributed uniformly in the network. The QoS parameter τ_n is chosen randomly from the interval $[0.5, 5]$ ms. The users have low mobility and can be assumed approximately static during the process time required for a matching. All the statistical results are averaged by 1000+ runs over random location of users and SCBSs, the channel fading coefficients, and other random parameters. The performance is compared with the max-SINR algorithm which is a well-known context-unaware approach exploited in wireless cellular networks for user-cell association. In this approach, each user is associated to the SCBS providing the strongest SINR.

Matching Game for Load Distribution in Multi-tier Cellular Networks, Fig. 1

Average utility per user for different number of PBSs with $N = 60$ users

Matching Game for Load Distribution in Multi-tier Cellular Networks, Fig. 2

Average utility per PBS for different number of users with $P = 20$ PBSs

Figure 1 shows the average utility per user as a function of the number of PBSs for $N = 60$ users. As the number of PBSs increases, the average load in each cell decreases. Consequently, the available resources for each user would increase. However, increasing the number of PBSs leads to an increase in the interference between the neighboring cells and, consequently, decreases the rate. Hence, as shown Fig. 1, the average utility per user is a decreasing function with respect to the number of PBSs. We can also see that, when the number of PBSs exceeds 30, the slope of the curves becomes less steep due to the fact that the matchings would not be affected by these increments as much as before. Indeed,

beyond this point, there are enough PBSs to serve all the users, and deploying more PBSs will not change the current matching dramatically. Figure 1 demonstrates that the proposed context-aware approach has a considerable performance advantage compared to the max-SINR approach. This performance advantage reaches up to 20.4% gain over to max-SINR criterion for a network with 30 PBSs.

Figure 2 shows the average utility achieved by each PBS as a function of the number of users for $P = 20$ PBSs. As the number of users N increases, the network becomes more congested, and the probability that a new user who applies for a PBS is coming from a

congested BS increases. Therefore, it is more likely for the PBSs to gain more utility by offloading the network. However, when the network is considerably congested, the new users that arrive to the network would be mostly assigned to the MBS, since many of PBSs are already servicing their maximum capacity. In this respect, Fig. 2 shows that, once the number of users exceeds 80, the average utility of PBSs remains constant. The proposed algorithm achieves up to 24.9% gain over the max-SINR approach when the number of users is 50.

Conclusions

In this work, we have proposed a new context-aware user association algorithm for the downlink of the multi-tier cellular networks. By introducing well-designed utility functions, our approach accounts for the trajectory and speed of the users as well as for their heterogeneous QoS requirements. We have modeled the problem as a many-to-one matching game with externalities, where the preferences of the players are interdependent and contingent on the current matching. To solve the game, we have proposed a novel algorithm that converges to a stable matching in a reasonable number of iterations. Simulation results have shown that the proposed approach yields considerable gains compared to max-SINR approach.

Media Access Control for Narrowband Internet of Things: A Survey

Yuyi Sun, Shibo He, and Fei Tong
The State Key Laboratory of Industrial Control Technology, Zhejiang University, Hangzhou, China

Introduction

Low-power wide-area network (LPWAN) has emerged as an attractive communication platform

for Internet of Things (IoT) (Eletreby et al. 2017). Among a variety of communication technologies in LPWAN, narrowband IoT (NB-IoT), standardized in the third generation partnership project in Release 13 (3GPP 2015), is a promising technology that attracts attention from both industry and academia. NB-IoT inherits long term evolution (LTE) and has its distinctive advantages, including (1) massive connections, (2) wide-area coverage, (3) low power consumption, and (4) low cost (Wang et al. 2017; Beyene et al. 2017; Zayas and Merino 2017).

Media access control (MAC) protocol in NB-IoT resolves channel collisions among multiple user equipments (UEs) (3GPP TS 36.211; 3GPP TS 36.331; 3GPP TS 36.321), by efficiently allocating channel resources of the evolved Node Bs (eNBs) to UEs. When there is a data transmission demand, a UE initiates random access procedure to occupy a channel and transmits data to an eNB. Clearly, random access protocol suffers from severe collisions when there are a large number of UEs in NB-IoT, leading to more power consumption. Therefore, it is significant to efficiently analyze the performance of random access in NB-IoT.

In LTE, MAC protocols can be divided into contention-free and contention-based MAC protocols, and here we focus on contention-based MAC protocols, i.e., contention-based random access procedure. Based on random access procedure, there are some existing models designed for LTE, which cannot be applied to NB-IoT directly since there are a large number of UEs in NB-IoT and meanwhile, wide-area is required. Having this in mind, we provide a survey of the existing MAC models for LTE and NB-IoT in this paper.

MAC for LTE

Random Access Procedure in LTE

Random access procedure in LTE consists of four steps: random access preamble, random access response (RAR), scheduled transmission, and contention resolution.

- *Random Access Preamble*: a UE selects one of the preamble sequences from two groups and transmits it to an eNB.
- *RAR*: after the eNB receives the preamble sequence, it transmits an RAR to the UE. If more than one UE selects the same preamble sequence, they will receive the same RAR.
- *Scheduled Transmission*: after receiving the RAR, the UE transmits/UEs transmit a message that contains a unique identity.
- *Contention Resolution*: if the eNB can decode one of the messages from scheduled transmission, it replies to the UE to transmit data.

MAC Models for LTE

Data transmission, power mechanism, and energy consumption are crucial to MAC for LTE. Previous studies have proposed different models to analyze such problems.

Markov chain was adopted to model random access procedure and analyze data transmission in LTE (Seo and Leung 2012). Based on semi-persistent scheduling (SPS) in random access for LTE, UEs are assumed to have an infinite buffer to store packets. Markov chain is used to model the SPS in LTE, including the states ON and OFF of the traffic source, the contention and transmission states of UEs. Equilibrium point analysis is investigated, obtaining the number of UEs in steady state, through which the probability of packet dropping is analyzed.

Power ramping mechanism was modeled during random access in LTE in terms of preamble signal to interference plus noise ratio (SINR) and preamble collisions (Misic et al. 2017). The ratio of external interference to received signal power is assumed as a Gaussian distribution, and the probability of missed preamble detection and the failure caused by eNB outage can be analyzed. Performance evaluation reveals that the downlink resources bring more success probability.

Zhao et al. (2017) reduced power consumption in a random access algorithm based on statistic waiting. After investigating random access procedure in LTE, they used slotted ALOHA to simulate packet transmission. A UE initializing random access procedure receives the success

rate of the last time slot, which helps the UE decide whether to transmit a packet or not and reduces energy consumption.

Previous MAC models in LTE cannot be directly applied to NB-IoT due to the following reasons: (a) there are three coverage levels defined by minimum coupling loss (MCL) in NB-IoT (Ng et al. 2009), which covers a wider range than that in LTE, requiring more retransmission times to achieve wide-area coverage. (b) Due to massive connected UEs in NB-IoT, a more efficient MAC model is needed to resolve a great deal of collisions. (c) Due to low-traffic rate and low-power consumption requirements, UEs in NB-IoT have a finite buffer to cache data packets, while LTE requires higher data rate. Thus, the length of buffer and larger retransmission number need to be considered simultaneously in NB-IoT to assign channel resources. We introduce the MAC models for NB-IoT in the next section.

MAC for NB-IoT

Random Access Procedure in NB-IoT

Random access procedure in NB-IoT also consists of four steps: random access preamble, RAR, scheduled transmission, and contention resolution.

- *Random Access Preamble*: a UE transmits a preamble to an eNB, which has a cyclic prefix and five symbols 1. Physical resources are configured based on MCL.
- *RAR*: after the eNB receives the preamble sequence, it transmits an RAR to the UE. If more than one UE transmits the same preamble sequence, they will receive the same RAR.
- *Scheduled Transmission*: after receiving the RAR, the UE transmits/UEs transmit a message that contains a unique identity, power headroom report, buffer states, and data volume.
- *Contention Resolution*: the eNB randomly selects a UE to decode its information received from scheduled transmission, then it replies to the UE to transmit data.

MAC Models for NB-IoT

Previous MAC models for NB-IoT mainly focus on coverage requirement and system throughput.

Lin et al. (2016) designed a frequency hopping pattern for NB-IoT with single tone random access channel signal. Based on the rationale of random access channel frequency hopping, the authors proposed corresponding receiver algorithms and time-of-arrival (ToA) estimation. Comparing the statistic value of ToA and a predefined threshold can help the eNB determine the presence of the preamble sequence. Simulation results reveal that the detection probabilities exceed 99%, which can meet the coverage requirement.

Based on probabilities characterization, first-in-first-out (FIFO) queue model, and Markov chain, a system throughput model was proposed and analyzed (Sun et al. 2017). Based on random access procedure, the UEs' buffer is denoted as a FIFO queue, and the probability that a FIFO queue is empty, the probability that a packet is transmitted successfully, and the probability that a channel is busy are characterized based on backoff mechanism. Markov chain is adopted to model retransmission number and queue length simultaneously to achieve the three probabilities in steady state. The expression of the system throughput can be obtained and calculated due to the three probabilities above. Extensive simulation results show that the number of UEs and the arrival rate of packets have obvious effects on system throughput, while the maximum retransmission number and the packet length have slight influences on the system throughput.

Harwahu et al. (2018) investigated a promising optimized random access model for NB-IoT. NB-IoT systems have three coverage enhancement (CE) levels due to different MCL. A UE initializes random access to occupy a channel from its initial CE level, which depends on the reference signal received power. When collisions happen, if the UE does not transmit successfully till the maximum retransmission number in this CE level is reached, it will switch to the next higher CE level to retransmit. When the global maximum retransmission number is reached, the UE will initialize random access again from its

initial CE level. Thus, in this entry, multiband multichannel slotted ALOHA is used to model this procedure. The first transmission and the retransmission at the same CE level and in the next higher CE level are analyzed. The optimization of random access for NB-IoT in this entry includes that: (a) more CE levels bring larger access success probability, (b) when the number of remaining retransmissions in a certain band is equal to the number of global retransmissions, access success probability increases, and (c) comparing number of successful UEs in each CE level and in their first transmission by exhaustive search can achieve the largest access success probability. Analytical model is supported by extensive simulations. The influences of parameters such as the number of UEs, the repartition ratios of subchannels, and retransmission times for different levels on the access success probability are analyzed.

In Li et al. (2018), an optimization to maximize the system throughput in random access narrowband cognitive radio IoT was introduced. This entry used slotted ALOHA to model random access procedure, including autonomous and collaborative sensing. With unique optimal detection probabilities in network level characterized, the throughput optimization of random access with autonomous sensing and collaborative sensing can be maximized. From the simulations, the system throughput with high signal noise ratio (SNR) and system interference tolerance is higher than that with low SNR and system interference tolerance. Autonomous sensing is better under high SNR, while collaborative sensing has a better performance under low SNR. The arrival rate of data is a Poisson process. Smaller arrival rate of data increases the maximum throughput rapidly and then, the maximum throughput reaches a peak, while larger arrival rate of data makes the maximum throughput decrease. As the arrival rate of data tends to infinity, the probability of detection converges to one, and the optimal probability of false alarm becomes a global optimal problem.

The NB-IoT development system in Chen et al. (2017) includes IoT cloud platform, NB-IoT development board, mobile phones, and appli-

cation server. The development board embeds the entire protocol of NB-IoT, including MAC and physical protocols. Based on the applicable system, practical experiments about MAC for NB-IoT can be done, which helps design efficient MAC models for NB-IoT.

Here we summarize the MAC models for NB-IoT in Table 1.

Conclusion

In this entry, we make a survey about the MAC for NB-IoT. Based on random access procedure, there are a lot of MAC models existing for LTE. However, such models cannot be applied to NB-IoT systems due to massive connections and wide-area coverage in NB-IoT. Thus, based on the features of NB-IoT, some works design new models for MAC in NB-IoT. In the future, some more parameters, such as the system latency, packet loss can be analyzed for the system performance of MAC for NB-IoT.

Acknowledgments This work was supported by NSFC under grant 61672458.

Definitions

Wireless Sensor Networks (WSNs) are composed of the interconnection, often through wireless links, of devices equipped with sensing, processing, storage, and communication capabilities. Such devices are called sensor nodes, and a WSN can contain tens to thousands of them. Sensor nodes are tiny in size, have reduced computational resources, and are usually battery-powered, thus making energy efficiency a crucial issue to extend the WSN lifetime. Each node contains one or more sensing units, capable of performing measurements of physical variables such as vibrations, acceleration, pressure, temperature, light, among others, converting them to digital signals. The sensors act in a collaborative way, extracting environmental data, performing simple processing, and transmitting them to one or more exit points, called sink nodes, gateways or base stations, to be analyzed and further processed. The data measured by the sensors and transformed into digital signals are translated into information about a phenomenon of interest to humans.

The term middleware, although very popular in computer science, can be a bit confusing to many people. One reason for this is the myriad of different types of middleware systems in use in the everyday software development tasks. In distributed systems, middleware is usually defined as an infrastructure software that lies between the underlying operating system, networks, and hardware and the applications running on each node of the system. In general, middleware is supposed to hide the lower-level hardware and internal operation and heterogeneity of the underlying system, providing standard interfaces, abstractions, and a set of services. Another role of middleware is to provide reusable set of services that can be combined and customized to create distributed systems faster and more reliably by integrating components that may be developed by different software infrastructure suppliers (Schantz and Schmidt 2001). By hiding the inherent complexity of distribution, the use of middleware in traditional distributed computing facilitates the work of application developers.

Tasks such as concurrency control, transactions, data replication, security, and other infrastructure services are examples of services performed by a middleware. In the context of WSN, the main purposes of a middleware are supporting the development and execution of sensing-based applications and managing the utilization of the network and sensor node's resources while meeting applications' requests.

Historical Background

Despite the well-known advantages of using middleware platforms in traditional distributed systems, only from the early 2000s the researchers began to consider its adoption in the WSN design (Bonnet et al. 2001; Capra et al. 2003; Delicato et al. 2003; Murphy et al. 2001; Shen et al. 2001). Considering the simplicity of the first applications and the application-specific nature of early WSNs, the overhead of adding a middleware layer in the network design was often not worth. Therefore, the first generation of WSNs was traditionally designed from scratch in a domain-specific and task-oriented fashion. WSN systems were built as monolithic software for a specific target platform and operating system and addressing the requirements of a single target application, with little or no possibility of reusing them for newer applications. However, to accommodate the new scenarios of shared and Internet-scale WSN systems, novel systematic design approaches based on high level and preferable standardized abstractions and services were required. Thus, the support of middleware for WSNs became a crucial need to provide: (i) appropriate **system abstractions**, so that application developers can focus on the application logic and not dealing with lower level implementation details, (ii) **standardized and reusable services**, so that developers can deploy and execute application without worrying about complex, error-prone, and tedious infrastructure-level functions, such as network and resource management, context-aware adaptation, among others, (iii) **runtime environment** able to manage the execution of

multiple applications. Middleware support is also necessary to provide interoperability between different WSN systems, with external networks, as the Internet, or with enterprise systems.

To meet such demands, from the 2000s several proposals of middleware systems specially tailored for WSN emerged, each with different goals and approaches. It can be said that database-based approaches (Bonnet et al. 2001; Madden et al. 2005; Shen et al. 2001) were the first attempt to propose a rudimentary middleware layer for the project of WSNs. In the COUGAR system (Bonnet et al. 2001), the processing capabilities of sensor nodes are used to perform part of the processing of queries within the network, instead of centralizing such processing only at the sink nodes. In Bonnet et al. (2000), an SQL-based declarative query language is proposed for users to submit their queries to the WSN. Also following this line, in Shen et al. (2001), an architecture for sensor networks called SINA is presented, which provides mechanisms for query, monitoring, and submission of tasks. SINA plays the role of a middleware that abstracts WSN nodes of an RSSF as a collection of distributed objects. Users access and extract information from a WSN either by issuing declarative queries or requesting tasks using programming scripts. SINA adopts the proprietary SCTL procedural scripting language as the interface between applications and the SINA middleware. An event-driven approach is adopted as a programming model.

From these early initiatives, most of which adopted approaches with little flexibility and generally tied to specific communication protocols, a myriad of new proposals for WSN middleware began to emerge, highly diversified regarding their design approaches, abstractions and programming models. Examples of approaches are (i) event-driven, (ii) service-oriented (Mohamed and Al-Jaroodi 2011), (iii) virtual machine-based, (iv) agent-based (Chen et al. 2006; Fok et al. 2005), (v) tuple-spaces (Costa et al. 2006), (vi) component-based, and (vii) application-specific (Heinzelman et al. 2004), with the first three being the most prominent ones. Some middleware platforms use a combination of approaches.

For example, many service-oriented middleware also employs VMs in their design and development.

Virtual Machine-based approach allows developers to write application code in separate, small modules that are injected and distributed throughout the network using specialized algorithms. The goal is minimizing the overall energy consumption and resource usage. The Virtual Machine (VM) in each node then interprets the injected modules. Examples of this approach include Maté (Levis and Culler 2002), ASVM (Levis et al. 2005), and DAViM (Michiels et al. 2006).

Another widely adopted programming approach to WSN middleware is based on the concept of events (Boonma and Suzuki 2012; Silva et al. 2014; Souto et al. 2004). In such approach, components, applications, and all the other participants interact through events. Applications specify their interest in given changes of state in the monitored environment (basic events). Upon detecting an event, a sensor node sends an event notification towards interested applications. The application can also specify patterns of events (composite events). Events are propagated from the event producers (sensor nodes), to the event consumers (applications).

Among the existing approaches, the service-oriented approach has been highlighted by providing innumerable advantages in the context of WSN middleware. The service-oriented design paradigm builds software or applications as services. Service-oriented computing (SOC) is based on the service-oriented architecture (SOA) and has been traditionally used in corporate information systems. The features of SOC, such as technology neutrality, loose coupling, service reusability, composability, and discoverability, are also potentially beneficial to WSN systems. Among its advantages, it can be mentioned that this approach offers a generic and flexible programming model that favors the interoperability between different applications and the network. By exposing the functionalities of the sensors as services, it offers a more flexible architecture in comparison, for example, with

databases approaches. SQL is basically a query language, not having a suitable semantics to represent the submission of tasks and actuation activities in the WSN.

Finally, Component-Based Software Engineering (CBSE) is a modern methodology that proposes software construction by plugging software components. Based on component interoperability, this programming approach aims at building more flexible and adaptable software. Recently, some middleware proposals based on CBSE have emerged in the WSN field (Costa et al. 2007; Man et al. 2016).

Foundations

WSN technology has made tremendous progress in the last decade, drawing the attention of the scientific community and industry. WSNs are the key components of the emerging Internet-of-Things (IoT) paradigm (Man et al. 2016). With their ability to instrument the physical environment, WSNs naturally constitute the core infrastructure from which IoT systems can be built for a myriad of domains. With the introduction of the IoT, it is envisioned that future WSN deployments will have to support multiple applications simultaneously. To enable this scenario, WSNs will have to evolve from application-specific systems to networks capable of sharing data and resources among several applications, in an efficient, fair, and transparent way. Of course, such sharing creates new challenges in promoting the interoperability of different sensor nodes and WSNs while achieving the desired energy efficiency and satisfying the requirements of multiple applications. Middleware is a technology that can potentially enable WSN sharing and provide solutions to these challenges.

In short, a middleware for WSN must provide support for the development, management, deployment, and execution of sensing-and-actuation-based application. Among other functions, the middleware can decide the best protocols to be used according to the application requirements, coordinate the operation of sensors

to achieve the application goals, and intelligently manage the use of device and network resources. To efficiently provide the quality of service required by applications, it is often necessary to interact with the lower levels of protocols or even with hardware components. Middleware services can be developed to perform this interaction on behalf of applications. The provision of all these functions by a middleware system facilitates the tasks of both the application developers and of the network managers.

Since WSNs have several distinct features and constraints, conventional middleware technologies are not suitable for these networks. Therefore, the development of new middleware systems, specifically tailored to WSN is required. The following paragraphs present a set of requirements that WSN domain poses on middleware system development.

Resource Constraint: WSN nodes are constrained devices regarding their processing power, memory capacity, bandwidth, and energy. The processing and memory constraints mean that any software solution for WSNs must be computationally light. Any protocol or algorithm for such networks needs to be designed aiming at the efficient use of available resources. The execution of application tasks must be performed in a way that balances the usage of resources and the meeting of QoS requirements. Moreover, since the battery life is limited, and the exchange or even recharge of batteries in a large-scale network is undesirable or even unfeasible, a key requirement of WSN is to have mechanisms to manage the energy consumption in sensor nodes in an intelligent way.

Scale: A single WSN may consist of hundreds to thousands of nodes and to efficiently manage this kind of computational environment is challenging. The traditional concept of network management captures methods and tools related to the operation, administration, maintenance, and provisioning of networked systems. However, to manage WSN systems, composed of heterogeneous nodes with different requirements and operational properties, a paradigm shift is necessary. Upper layers need to efficiently capture dynamic system changes, and lower layers need to transform that information into

appropriate, autonomous, and scalable actions. In recent years, several extensions have been proposed for the traditional definition of systems and network management, which are specifically designed to address the increasing complexity and dynamism of these environments. Besides controlling the network operation, the high number of nodes will require mechanism to coordinate them in the execution of the required sensing tasks.

Heterogeneity: The WSN environment is composed of devices, communication links, protocols, and software components that are heterogeneous in terms of capabilities, programming abstractions, models, and development tools. Such heterogeneous nature of WSNs emerges not only from differences in capacity and features but also for other reasons including multivendor products and application requirements. Such heterogeneous environment with many sensors of different hardware platforms running applications developed by different teams will require using an abstraction layer that provides a common way to program, access the networks, and extract the sensing data.

Data Processing: Sensors generate a huge amount of data, typically consisting of time-series values, which are sampled over a specific period of time, thus characterizing a data stream. The input rate of a data stream ranges from a few bytes per second to a few gigabits per second. Such rate can be irregular, unpredictable, and bursty in nature. In addition, sensor data are subject to different degrees of accuracy. The network, by its very nature, has only the ability to sample physical processes, which in turn implies that the obtained result approximates the real parameters observed. Therefore, the data in WSNs have an extra dimension, namely, the accuracy. In this context, accuracy can be defined as the degree to which the value provided by the sensors approaches the “real” value of the monitored physical phenomenon. Some factors that contribute to the accuracy of the data measured by a sensor are its nominal accuracy (from the manufacturer) and its distance from the phenomenon, in addition to environmental noise.

Diverse application: WSN-based systems can offer its services to many applications in numer-

ous domains and environments. Different applications are likely to need different deployment architectures (e.g., event-driven and time-driven), have different requirements, and often must be served with different priorities. For instance, time critical and mission critical applications demand some level of priority in the access to the shared resources, in detriment of non-critical applications.

Context-awareness: Context is key in WSNs and their applications. A large number of sensors will generate large amounts of data, which will not have any value unless they are analyzed, interpreted, and understood. Context-aware computing stores context information related to sensor data, easing its interpretation. More specifically, location or spatial information about sensors is critical, as location plays a vital role in context-aware computing. In a large-scale WSN, interactions are highly dependent on their locations, their surroundings, and presence of other entities (e.g., other systems, neighboring nodes, and people).

Dynamicity: WSNs are subject to unpredictable changes in their execution context. Besides the intrinsic variations in the network connectivity, typical of wireless links, the availability of sensors in the network is also highly variable due to node failures, energy depletion and mobility. The network topology is also frequently changed by topology control protocols that decide when and which sensors should be turned off to save power. Within such an ad hoc environment, where there is limited or no connection to a fixed infrastructure, it will be difficult to maintain a stable network to support many application scenarios. Nodes will need to cooperate to keep the network connected and active. Moreover, the required sensing tasks, that dictate the network behavior, can also change since the emergent WSN are assumed to be used by different applications (concurrently or not). These characteristics demonstrate the high degree of dynamism in the execution context of WSNs. Therefore, it is crucial that such networks are endowed with mechanisms that provide context-awareness and adaptation.

Data-Centricity: Sensor nodes are used to collect data from its surroundings. Since

applications are interested in the data collected by a sensor and express their interests in terms of type of data and QoS requirements, the scheme for node addressing in a WSN should be based on attributes that describe the node capabilities to provide data, instead of using a scheme based on any global and unique network address. Moreover, individual readings of a node are often not relevant to the application, which is more interested in the merged or synthesized information gathered from different nodes. Considering the typical spatial density in a WSN, there is often a redundancy in the data collected for different nodes inside a given region of interest. Since communication is in general more energy consuming than data processing, individual measurements should be aggregated as near to the data source as possible so that only the resulting, relevant information is transmitted to sink nodes. Therefore, in-network, data-oriented processing should be performed in every node of the WSN, aiming at reducing data redundancy, increasing the relevance of the information reported back to the application and saving energy.

Security Issues: Since WSN can be deployed for sensitive applications like military surveillance and forecasting systems, security requirements such as confidentiality, authentication, integrity, freshness, and availability should be considered. Since most existing algorithms and security models are not suitable for WSNs, solutions specifically tailored for these networks must be designed that consider the node resource constraints.

WSN Middleware Services

All services provided by the middleware must respect the intrinsic characteristics of WSNs, especially scalability and energy efficiency. The middleware should provide robustness/fault tolerance and adaptability features to deal with the dynamic execution context of WSNs and the intermittence of wireless connections. Given the data-driven nature of these networks, middleware must provide data-centric mechanisms for processing and querying data within the network. In addition, application-specific knowledge can

be used to optimize network operation, while sharing resources across multiple concurrent applications. Due to the restricted capabilities of nodes, the middleware must be light in terms of its communication and processing demands. The main services to be provided by a WSN middleware are described as follows.

Resource Management: WSN middleware should provide services to manage and optimize the network resource usage in an efficient way while meeting the application requirements. One example of such services is to select the set of nodes that will participate in a given sensing task, always considering the tradeoff between meeting the application requirements and optimizing energy consumption. Another useful service is to implement data fusion techniques to merge sensor readings of individual sensors into a high-level result to be sent to the application, thus saving transmission energy while increasing the data accuracy.

Context Management and Dynamic Adaptation: Considering the high dynamism of WSN environments, in which devices may become unavailable for a variety of reasons, middleware platforms must provide strategies for dynamic adaptation, thus ensuring the availability and quality of the applications during their execution. This is particularly important for applications in critical domains, since flaws or degradation of quality parameters in such applications can be a threat to human life and health. Thus, WSN middleware must remain available and functioning properly in this dynamic environment. To do so, it needs to provide mechanisms for collecting and analyzing contextual data, and responding to changes in the execution context, without decreasing the WSN system overall performance. Adaptive measures must be applied whenever the target operational performance metrics are not met. Examples of adaptive actions are turning on/off sensors, changing the data sensing/sending rates, enabling/disabling data aggregation functions, and changing the routing protocol in use on the network. QoS metrics and adaptation plans are managed by the middleware via policies and rules predefined by applications.

Resource and Service Discovery: WSN resources are very heterogeneous, including from low-level processing, communication, and sensing capabilities of individual sensor nodes to high-level services such as processed data and complex events detected from analyses of raw sensing data. For applications to make use of these resources, middleware must provide mechanisms for their discovery. In addition, in the absence of network infrastructure (since WSN are often ad hoc in nature), the middleware must provide two levels of service discovery. The internal level of discovery is used so that the sink nodes are aware of all the capacities of the sensor nodes that make up the network. Likewise, neighbors must know each other's resources. This is done by advertising mechanism that may rely on protocols and data formats common within a same WSN. The external level of service discovery is used by an application to find out which WSN provide the services it requires and how to access those services. In this case, the middleware should provide a standardized interface to access the WSN resources, abstracting its specific formats and protocols. Considering the dynamic environment of WSNs, assumptions related to global and deterministic knowledge of the resources' availability do not hold. Moreover, considering the high scale and geographical features of the WSN deployment, human intervention for resource discovery is infeasible. Therefore, an important requirement for WSN middleware is providing automatic resource discovery, based on high-level descriptions of application functional and QoS requirements.

Code management: Deploying code in a WSN environment is challenging and should be directly supported by the middleware (Razzaque et al. 2016). In particular, code allocation and code migration services are required. Code allocation selects the set of devices or sensor nodes to be used to accomplish a user or application-level task. Code migration transfers one node's code to another, potentially reprogramming nodes in the network, for instance to address requirements of arriving applications in a dynamic way. Approaches such

as VM and agent-based help provide this type of service, since they offer a common execution environment to run migrated code.

In addition to these, there are several generic services that a WSN middleware can provide, such as: naming, location, security, and time synchronization.

Key Applications

Military applications such as target detection, battlefield surveillance, and counterterrorism originally motivated WSN applications. However, sensor nodes are very flexible and can be used for continuous data sensing, event detection, and local actuator control, as well as other tasks. The advantages of WSN over traditional networks resulted in many other potential applications, ranging from infrastructure security to industrial/factory control, environment and habitat monitoring, healthcare applications, home automation, and traffic control. The design and development of a successful middleware must address challenges posed by WSN features on one hand and the application demands on the other hand.

Definition

Beam training is the search procedure that the transmitter and/or the receiver selects one or multiple beams from its beam training codebook (a set of predefined beams), so as to achieve the necessary link budget for subsequent communications via transmitting or receiving signals with these beams. Beam tracking is the adjustment procedure that the transmitter and/or the receiver adjusts its beams to guarantee the link stability for time-varying propagation environment. Beam training and tracking are usually used in the millimeter wave communications to combat the severe path-loss of signal propagation and the user mobility, respectively.

Historical Background

Millimeter wave (mmwave) communications operating in the band of 30–300 GHz has attracted much attention recently and also been recognized as a promising technology for future mobile networks, owing to its abundant spectrum resources (Xiao et al. 2017). However, the propagation of mmwave signal usually suffers a large path-loss, which severely limits the coverage range of mmwave communications. To address this issue, large antenna arrays are usually equipped in the mmwave communication system, so that the array gain can be exploited to combat the path-loss and increase the communication distance (Heath et al. 2016). Thanks to the short wave length of mmwave signals, it is possible to pack a large number of antennas into a compact size.

Due to the large path-loss of mmwave signals, the necessary link budget usually cannot be satisfied before achieving the array gain provided by the large antenna arrays. Therefore, at the beginning of communications, it is essential for the transmitter and the receiver to determine their respective beams, so as to achieve the array gain and build reliable communications links (Zhang et al. 2017a). To achieve this goal, beam training is designed to select the preferred transmit beam and/or the preferred receive beam from their

respective beam training codebook, i.e., a set of predefined beams. Beam training plays a key role in mmwave communications due to its importance in building reliable mmwave communication links, acquiring channel state information (CSI), achieving desired rate of data transmission, and enlarging the cell coverage area.

As a viable approach, beam training was adopted in mmwave multi-gigabit wireless local area network (WLAN) (Tsang et al. 2011) and wireless personal area network (WPAN) (Wang et al. 2009), where analog antenna array architecture and analog beams were considered. Compared with the straightforward method, i.e., to exhaustively train all possible beams in the codebook, then to find the best one or several beams for transmission, a hierarchical-search-based beam training scheme was proposed in Hur et al. (2013) to reduce the training overhead based on multi-resolution or variant beamwidth analog beams. Specifically, all possible wide beams are first trained and the best is selected. Then the beams with narrower beamwidth are trained within the coverage range of this selected best wide beam and the best is chosen. This procedure is repeated until the optimal beam with acceptable beamwidth is found. Later, to improve the accuracy of the hierarchical-search-based training scheme while still maintain its low training overhead, a beam training codebook for the analog architecture was devised in Xiao et al. (2016) by exploiting subarray and deactivation antenna processing techniques. To address the problem of error propagation in hierarchical-search-based training schemes, a novel design of training codebook was proposed in Zhang et al. (2017a) based on the hybrid antenna array architecture, which can provide more flexibility in designing training beams compared to the analog architecture (Alkhateeb et al. 2014). To further reduce the training overhead, a beam training approach was proposed in (Kokshoorn et al. 2017), based on overlapped beam patterns. The beam training approaches aforementioned are mainly designed for single data stream transmission. To enable multiple data stream transmission, a cooperative multi-subarray beam training approach was proposed in Zhang

et al. (2017b) recently for a codebook-based beamforming system.

All the abovementioned beam training schemes correspond to decoupled transmission design (called non-interleaved training) since the complete effective CSI should be obtained first for the full or selected partial beam codebook. When the size of the training beam codebook is comparative to the BS antenna number for satisfactory performance, heavy training overhead is unavoidable. The decoupled nature of non-interleaved schemes thus imposes limitations on the trade-off between training overhead and performance. In Zhang et al. (2018), an interleaved training design was proposed to achieve favorable trade-off between the outage performance and the training overhead where the BS and/or users monitors the training procedure to avoid training redundancy, i.e., to find just enough beams to avoid an outage; thus, the training length depends on the channel realization, and the termination of the training process depends on previous training results, leading to smaller average training overhead.

To achieve a large array gain, the beamwidth of the training beams shall be narrow, and thus the size of the beam training codebook could be large, which leads to a significant beam training overhead. This problem becomes even more serious for the mobile mmwave scenario, since there may be no enough time to perform beam training repeatedly. To address this issue, it is necessary to resort to beam tracking, which is realized by appropriately adjusting the beam directions. Beam tracking has been studied for a long time. The first beam tracking approach in mmwave communication (Wang et al. 2009; Kim and Lee 2015) also finds the candidate beams besides the desired ones in each training and then checks the feasibility of candidate beams in the next training. If some time-varying models are assumed, other beam training approaches can be used for beam tracking as well. Recently, beam tracking solutions based on conventional Kalman filter have drawn considerable attention, by exploiting the temporal correlation of time-varying channels (Jayaprakasam et al. 2017; Zhang et al. 2016; Va et al. 2016).

Foundations

Beam training is a viable approach to achieve the goals of building reliable mmwave communication links, enlarging the coverage area and so on in mmwave communications. In fact, beam training has been widely used in practice and adopted by some communication standards, e.g., IEEE 802.11ad and IEEE 802.15.3c. To better illustrate the principle of beam training and tracking, we take the scheme of single-beam training in IEEE 802.11ad as an example.

Beam training, termed as beamforming (BF) training in the IEEE 802.11ad, is a mechanism used by a pair of stations (STAs), e.g., one transmitter and one receiver, to achieve the necessary link budget for subsequent communication. It consists of three phases, i.e., sector-level sweep (SLS), beam refinement protocol (BRP), and beam tracking. An example of BF training procedure is provided in Fig. 1 for clarity. The STA that initiates BF training is referred to as the initiator, and the recipient STA that participates in BF training with the initiator is referred to as the responder. BF training starts with a sector-level sweep (SLS) from the initiator. The purpose of the SLS phase is to enable communications between the two participating STAs. To accelerate the speed of beam training and further reduce the training overhead, in the stage of SLS, the beams with wide beamwidth are considered at first, as shown in Fig. 2a. The SLS procedure of the BF training is presented below in details.

Sub-phase 1: In this sub-phase of SLS, the initiator uses sector-wide beams in turn to sweep its beam space, while the responder receives the transmitted signals using omnidirectional or quasi-omnidirectional beam, as shown in Fig. 3. Based on the received signals, the responder can determine the best sectorized transmit beam of the initiator. Moreover, the index of the best sectorized transmit beam should be fed back to the initiator.

Sub-phase 2: As shown in Fig. 4, sector-wide beams are used in turn by the responder to sweep its beam space, while omnidirectional or quasi-omnidirectional beam is used by the initiator to receive signals. Based on the received signals,

Millimeter Wave Beam Training and Tracking, Fig. 1 An example of beamforming training in IEEE 802.11ad

Millimeter Wave Beam Training and Tracking, Fig. 2 Beam training in IEEE 802.11ad: (a) sector-level sweep; (b) beam refinement protocol

Millimeter Wave Beam Training and Tracking, Fig. 3 Beam training in IEEE 802.11ad – sub-phase 1 of SLS

the initiator can obtain its best sector transmit beam. Moreover, the initiator can determine the best sector transmit beam of the responder and should feedback the index to the responder.

Sub-phase 3: The initiator uses the best sector transmit beam obtained in sub-phase 2 to transmit signals, as shown in Fig. 5. The responder uses

sector-wide beams in turn to receive signals. Based on the received signals, the responder can obtain its best sector transmit beam and also determine its best sector receive beam.

Sub-phase 4: In this sub-phase, the responder uses its best sector transmit beam to transmit signals, while the initiator uses sector-wide beams

 sub-phase 4 of SLS

to receive signals, as shown in Fig. 6. Based on the received signals, the initiator can determine its best sector receive beam.

When the four sub-phases of SLS aforementioned are finished, both the initiator and the responder can determine their best sector transmit and receive beams. Next, a beam refinement protocol (BRP) may follow, if requested by either the initiator or the responder. The purpose of the

BRP phase is to enable iterative refinement of the antenna weight vector of both transmitter and receiver at both participating STAs. In the phase of BRP, the beams with narrow beamwidth are considered, as shown in Fig. 2b. The training procedure in this phase is similar to that in the SLS.

Beam tracking can effectively reduce the training overhead, especially for mmwave mobile

environment. Similarly, a relatively simple beam tracking approach, which is a simplified and improved version of the beam training approach in (Wang et al. 2009), is used to show the basic principle and operational procedure. Due to its quite low complexity and easy implementation, the beam tracking approach has been adopted in current mmwave communication standard, e.g., IEEE 802.11ad. The key idea is to select several candidate beams (or beam pairs) instead of only the optimal beam (or beam pair), during the beam training procedure. For example, when the beam pair with the highest SNR is selected, the beam pairs having the second and third highest SNRs are also retained. When the channel varies, only the candidate beam pairs are tested and switched on to keep the SNR above a certain threshold. The complete beam training procedure is performed, only when all the candidate beam pairs fail. In IEEE 802.11ad, the beam refinement is performed periodically to track beam directions in the third phase.

It should be pointed out that in the literature, there also exist other beam training schemes, which can further improve the performance of beam training. However, most of these beam training schemes are extended from the schemes standardized in IEEE 802.11ad or IEEE 802.15.3c. Moreover, these beam training schemes require carefully designed training codebooks. We would like to recommend readers to refer to Zhang et al. (2017a), Tsang et al. (2011), Wang et al. (2009), Hur et al. (2013), Xiao et al. (2016), Alkhateeb et al. (2014), and Kokshoorn et al. (2017) for details.

The beam training and tracking approaches aforementioned are mainly applied to the case of single data stream. It is very desired to transmit multiple data streams simultaneously in practice. In this case, if conventional beam training schemes are still used, the resulting complexity and training overhead may be prohibitive. To address this issue, the idea of multi-subarray cooperation was introduced in Zhang et al. (2017b), where a codebook-based beamforming mmwave system was considered. It is recommended to refer to Zhang et al. (2017b) for more details.

Key Applications

Millimeter wave wireless local area networks (WLAN), 802.11ad, 802.11aj, 802.15.3c; wireless display; virtual reality or enhanced reality; automatic sync applications (e.g., uploading images from a camera to a PC); millimeter wave cellular networks.

Millimeter wave multiple access

Definition

Millimeter wave (mmWave) channel access is the technology that enables more than one users connected to the same system resource block for

concurrent transmission in wireless communications networks operating at mmWave band.

Historical Background

Channel-access technologies are used for supporting multiple-user wireless communication over networks. Several fundamental types of channel access schemes have been widely investigated in Sub-6 GHz microwave wireless communications. For example, in frequency division multiple access (FDMA), time division multiple access (TDMA), and code division multiple access (CDMA), multiple users utilize different frequency bands, time slots, and codes, to establish their own links with the base station (BS), respectively (Goldsmith 2005). These orthogonal multiple access (OMA) technologies have been already utilized in Sub-6 GHz communications systems such as 3G/4G mobile communications systems. They are also applicable to mmWave wireless communication systems. For example, the 802.11ad standard operating at 60 GHz mmWave spectrum adopts the TDMA Scheme (802.11ad 2012).

Compared with these OMA schemes, nonorthogonal multiple access (NOMA) schemes are less used in existing wireless communications standards. As a typical spatial-domain NOMA technology, spatial division multiple access (SDMA) was introduced in 1990s (Roy and Ottersten 1991) (Fig. 1). In SDMA, different beams are used to transmit messages of different users within the same resource block (e.g., time-frequency block), and each beam is optimized to make sure a large signal gain for its dedicated user and small gains for other users. The SDMA scheme has been already supported in the LTE standards since LTE Release 8 (Technical Specifications n.d.), and IEEE 802.11 ac is the first major wireless communications standard to integrate the SDMA scheme (Wireless LAN Medium Access Control 2011). Massive MIMO is the latest technology along this direction (Rusek et al. 2013), in which the BS is equipped with large-scale antenna arrays, e.g., with hundreds of antennas, to serve tens of users via SDMA. In massive MIMO systems operating

Channel Access, Fig. 1**
SDMA for K users

**Millimeter Wave
Channel Access, Fig. 2**
Two-user SISO-NOMA systems

at Sub-6 GHz, due to massive antennas at the BS and relatively rich scattering in the propagation, users' antenna-domain channels become less nonorthogonal. This enables high user multiplexing gains, even with simple linear precodings, e.g., maximum ratio transmit (MRT) and zero-forcing (ZF), at the BS (Zhang et al. 2017a).

Another NOMA technology under the spotlight in academic is the power-domain NOMA (usually called NOMA for short), which has been considered as one of the candidates for improving the spectral efficiency and connectivity density in 5G communications (Ding et al. 2014; Dai et al. 2015). The 3rd Generation Partnership Project (3GPP) (a collaboration between groups of telecommunications standards associations) also considers NOMA as a candidate channel-access technology in 5G communications and discussed it at RAN plenary #66 in the name of Multi-User Superposition Transmission (MUST) (<https://portal.3gpp.org/desktopmodules/Specifications/>

[SpecificationDetails.aspx?specificationId=2912](https://portal.3gpp.org/desktopmodules/Specifications/SpecificationDetails.aspx?specificationId=2912)). In conventional single-input-single-output (SISO) NOMA systems with single-antenna BS and users, different signals from different users are superimposed on each other at the BS. Multiple users share the same resource block and detect their signals via successive interference cancellation (SIC). Specifically, as shown in Fig. 2, for a two-user SISO-NOMA system, the BS serves a far-end user U1 and a near-end user U2, both users share the same resource block with a certain transmit power allocation $P_1 > P_2$. Under this scheme, user U1 decodes its own message by directly treating the message of user U2 as the background noise, while user U2 first decodes the message of user U1 and then decodes its own message after removing the message of user U1. It has been shown that the spectral efficiency can be enhanced at the cost of an increased receiver complexity compared to conventional OMA systems, and larger gaps among users' channel gains and better

Millimeter Wave Channel Access, Fig. 3 Random access procedure in Sub-6 GHz cellular networks

power allocation policy are both beneficial to the performance of NOMA systems (Zhu et al. 2017; Wang et al. 2017a).

The above-introduced channel-access technologies are mainly used in the data transmission stage. In other communication control stages, e.g., the initialization of user access and cell handover, the random access technology plays an important role. As shown in Fig. 3, four steps in the random access procedure in Sub-6 GHz cellular networks are as follows (Jeong et al. 2015): In step 1, the user transmits one selected preamble signature to the BS by using the resource block indicated in the system information broadcast by the BS. In step 2, if the BS successfully detects the user's preamble, it transmits the random-access response to the user, including the index of the detected preamble sequence, the uplink timing information, and the indication of the resource allocation for the next step. In step 3, the identity of the user is transmitted to the BS. Finally, in step 4, the identity of the user is transmitted back to the user from the BS to confirm that the random access procedure is successfully completed for the user.

Foundations

Since shorter wavelengths at the mmWave band make it easier to equip massive antennas in the same physical space, massive MIMO

becomes the representative technology to build up mmWave communication systems. Due to the large spatial degrees of freedom in massive MIMO, the spatial resolution-based channel access technologies are of great importance. In what follows, the new features of channel and system structures in mmWave massive MIMO systems which affect the design of channel access will be first introduced. Then, the application of SDMA and its combination with NOMA and random access will be subsequently discussed for mmWave massive MIMO systems.

Features of mmWave Channel and System Structures

Compared to the Sub-6 GHz systems, in mmWave massive MIMO systems, channels become spatially sparse and highly directional due to limited scattering. This, however, results two adverse effects. On one hand, different users' antenna-domain channels become less orthogonal due to the reduced effective channel dimensions, especially for users with similar locations. On the other hand, channel powers are distributed in fewer scatterers, which indicates that using partial channel scatterers, e.g., via directional beamforming, for transmission results in smaller performance losses. In addition, the mmWave channel is typically with a large path loss, and this undesirable physic demands a large array gain. Moreover, due to their hardware costs and power consumptions, as shown in Fig. 4, one typical structure of mmWave massive MIMO systems is the hybrid analog/digital one with limited RF chains and phase shifter networks. Under this structure, fewer degrees of freedom are available for beamforming design, especially for the practical low-resolution phase shifters, leading to a coarser beamforming capability.

SDMA in mmWave Systems

Under the hybrid beamforming structure, its coarser beamforming capability results in a weaker capability of user interference suppression. Meanwhile, due to the channel nonorthogonality in antenna-domain, popularly used linearly precoding methods in Sub-6 GHz massive MIMO systems may have nonnegli-

Millimeter Wave Channel Access, Fig. 4 MmWave massive MIMO system with hybrid beamforming and limited scattering channels. D/A is digital to analog converter. Up-converter moves the frequency of the input signal to

higher frequency. One phase shifter network includes the same number of phase shifters as the number of antennas. PA is the power amplifier

gible performance degradation. Furthermore, another factor making designs of SDMA more challenge is the incompleteness of channel state information (CSI) at the BS. Specifically, due to the possible low prebeamforming signal-to-noise-ratio (SNR), massive antennas, and limited RF chains, the mmWave massive system tends to possess only partial or long-term CSI at the BS. Practically, the beamforming design should be based on long-term channel statistics (channel direction and spatial profile of average channel power) and the beamspace CSI, i.e., instantaneous effective CSI for limited analog beams (each analog beam corresponds to one phase setting of one phase shifter network). Therefore, the mmWave channel characteristics, the less flexible hybrid structure, and the CSI incompleteness at the BS independently or jointly make the transmit precoding/beamforming and receive combining (when users also have multiple antennas) more challenging (Sun et al. 2016).

Some effective hybrid beamforming algorithms have been proposed to guarantee a desirable SDMA performance. For example, in Alkhateeb et al. (2015), a decoupled baseband/analog design was proposed where by ignoring the user interference, the BS first finds the best beam for each user via beam training (Zhang et al. n.d.) and then conducts the baseband digital beamforming to reduce the residual user

interference based on beamspace CSI. In Li et al. (2017), the capacity of beamspace channel is used as the optimization object for beamforming design, while the analog beamforming is achieved based on channel statistics only. In He et al. (2017a), the codebook (with finite analog beams)-based hybrid beamforming optimization is simplified to a joint codeword selection and beamforming design problem where both the baseband and analog designs are achieved based on complete beamspace CSI.

Spatial Sharing Multiple Access

The spatial sharing-based multiple access has been adopted into the wireless local area networks (WLAN) standard 802.11 ad (Hany and Widmer 2017). Similarly, for wireless personal area network (WPAN) standard 802.15.3c operating at mmWave bands (Baykas et al. 2011), many researchers are also interested in applying this spatial sharing idea to increase system throughput. Specifically, via utilizing the high propagation loss and antenna directionality, multiple links (each link is made up of one transmitter and one receiver) are scheduled to transmit concurrently in the same time slot. This combination of spatial sharing-/reusing-based multiple access with the original TDMA is named the spatial time division multiple access STDMA (Qiao et al. 2012) (Figs. 5).

Millimeter Wave Channel Access, Fig. 5

STDMA in WPAN. The piconet coordinator (PNC) provides the basic timing for the piconet with the beacon and manages QoS requirements, power save modes, and access control to the piconet

User Scheduling

The performance of SDMA is highly dependent on channel characteristics. For example, in typical mmWave network situations where users are in similar locations and near line-of-sight (LoS) channels exist, SDMA can only avoid large user interference via extremely fine beamforming. These mmWave channel characteristics make the user scheduling necessary, i.e., it is more practical to serve some users via SDMA and other users in orthogonal system resources. Practically, due to the aforementioned CSI incompleteness at the BS, the user scheduling should be based on the long-term channel statistics (Zhang et al. 2017b) and/or partial beamspace CSI (He et al. 2017b). Therefore, the optimal user scheduling for mmWave hybrid massive MIMO systems involves the joint design of user selection, analog beam assignment/design, and baseband digital beamforming, which is more complicated than its counterpart of Sub-6 GHz systems. In He et al. (2017b), the limited beamspace CSI-based joint analog beam selection and user scheduling task is formulated as a nonconvex and combinatorial optimization problem, and two codebook-based low-complexity methods are proposed to address this problem.

For the STDMA transmission, the optimal concurrent transmission scheduling problem can be converted to a Knapsack problem which is NP-complete (Pisinger 2005). In Sum et al. (2009), multiple communication links are scheduled within the same time slot if the

accumulated interference in this slot is below a specific threshold. In Qiao et al. (2012), the scheduling design is optimized to maximize the number of concurrent flows such that the quality of service (QoS) requirement of each flow is satisfied. This optimization problem is decomposed and solved via a heuristic scheduling algorithm.

MIMO-NOMA in mmWave Systems

With multiple antennas at the BS in mmWave systems, the combination of NOMA and MIMO becomes a natural choice. It has been shown that (1) NOMA can achieve a higher channel capacity than OMA in both mmWave uplink and downlink systems (Naqvi and Hassan 2016); and (2) Enormous capacity improvement can be achieved by mmWave MIMO-NOMA, compared to existing LTE systems (Zhang et al. 2017c). In mmWave MIMO-NOMA, more than one users can be simultaneously supported in each beam via superposition coding and SIC operations. This is different from the conventional SDMA, where the signal for one user is only transmitted in each beam (Ding et al. 2017; Wang et al. 2017b). On the other hand, the small amount of RF chains in mmWave hybrid massive MIMO systems further limits the number of available beams and supported SDMA users. Consequently, much more users can be served within the same system resource block for any given RF chains via mmWave MIMO-NOMA,

Millimeter Wave Channel Access, Fig. 6

MIMO-NOMA system with two clusters: Each cluster includes two users covered by the same beam

and the system achievable sum-rate can be also improved Fig. 6.

The main challenges in mmWave MIMO-NOMA are given as follows (Xiao et al. [n.d.](#); Huang et al. [n.d.](#)). Similar to SISO-NOMA, SIC in mmWave MIMO-NOMA is implemented at the user side to suppress interference. While power allocation among users is the main focus in SISO-NOMA, it is possible to eliminate the user interference via beamforming and SIC in both the power and spatial domains in mmWave MIMO-NOMA, resulting in a more complicated design problem. For example, in SISO-NOMA, the SIC order generally depends directly on channel gains, e.g., a user with a smaller channel gain has a higher SIC order (i.e., decoded first). However, in mmWave MIMO-NOMA, effective channel gains are affected by beamforming designs. This results in a coupled beamforming and SIC ordering optimization. Moreover, some features in mmWave massive MIMO systems, e.g., massive antenna arrays, channels with limited scattering, and hybrid beamforming structures, make existing designs for the conventional MIMO-NOMA less applicable.

Due to the coarse hybrid beamforming capability and limited RF chains in mmWave systems, it is hard to serve many users only based on spatial resolution, especially for users with near directions. Introducing NOMA into mmWave MIMO can provide possibility of simultaneously serving these users. This advantage is of significant importance for those scenarios where both high data rate

and massive connectivity, e.g., dense urban scenarios, are highly desired. Furthermore, the increased path-loss component (Naqvi and Hassan [2016](#)) and channel blocking effect in mmWave communications are both beneficial for NOMA performance since they result in a larger channel gain difference for users covered by one beam with near locations. Considering the abovementioned two harmonies between the mmWave systems and the principle of NOMA, the use of NOMA for mmWave communications is a promising research direction.

Random Access in mmWave Systems

The basic procedure of random access in mmWave systems is similar to that of the traditional Sub-6 GHz cellular network, as shown in Fig. 3. However, in an mmWave cellular network, highly directional beamforming should be used at both the BS and users to compensate the large channel path loss. Since random access cannot benefit from the full beamforming gain due to the lack of information on the best transmit-receive beam pair (i.e., the location of strongest channel scatterer), the design of the random access becomes more challenging in mmWave communication systems (Jeong et al. [2015](#); Polese et al. [2017](#)). It has been shown that the exhaustive directional beam pair search is able to achieve a better preamble detection than the omnidirectional beam at the same cost of time overhead (Jeong et al. [2015](#)). Furthermore, reducing the time overhead of random access can be achieved by, e.g., (1) using enhanced preamble

detection method; (2) steering multiple receive beams in the same direction simultaneously to increase power of the received signals via noncoherently accumulation; (3) exploiting beam reciprocity to utilize the downlink beam information for the uplink; and (4) having better cell deployments for stronger channels (Jeong et al. 2015). Some other approaches directly aim to reduce the time overhead of the naive exhaustive search in random access for mmWave systems. For example, the angular space can be scanned in time-varying random directions using synchronization signals periodically transmitted by the BSs (Barati et al. 2015), the two-stage hierarchical procedure can be employed to speed up user discovery (Desai et al. 2014), and the context information on users and/or BS positions provided by a separate control plane can be also used to accelerate the random access procedure (Shokri-Ghadikolaei et al. 2015).

Key Applications

TDMA has been adopted in 802.11ad WLAN standard and 802.15.3c WPAN standard; spatial sharing multiple access has been used in 802.11ad WLAN standard; SDMA (multiple-user MIMO) has been added into 802.11aj WLAN standard (Complete Proposal for IEEE 802.11aj (45 GHz) n.d.; Hong et al. 2018) and is likely to be used in 802.11ay WLAN standard (an improved version of 802.11ad) (http://www.ieee802.org/11/Reports/tgay_update.htm).

Definitions

Channel measurement refers to the techniques widely used in telecommunications for studying the properties of wireless channels. It is done by carrying out real-world measurements using a set of specialized equipment known as channel sounders (transmitter(s) and receiver(s)). Typically, the field measurements are undertaken at different times, cities, environments, and under

different scenarios, resulting in what is referred to as channel measurement campaigns. The results from the measurements are used to develop channel models for the characterization and performance evaluation of wireless systems and networks. Millimeter wave (mmWave) channel measurements thus refer to measurements carried out at mmWave frequencies (30–300 GHz) (Busari et al. 2017).

Key Points

The mmWave frequency bands fall in the extremely high frequency (EHF) range of the electromagnetic spectrum. The bands have frequencies (f) spanning [30, 300] GHz, which corresponds to wavelengths (λ) of [10, 1] mm, respectively, as $f = c/\lambda$ and $c = 3 \times 10^8$ m/s is the speed of light (Busari et al. 2017). While this is the general range for mmWave, some authors in the literature limit the mmWave frequencies to the 30–90/100 GHz bands, preferring to refer to the 90/100–300 GHz frequencies as part of the terahertz (THz) bands (Mumtaz et al. 2017a). In addition, frequencies above 6 GHz but lower than 30 GHz, such as frequencies between 10 and 28 GHz, are also referred to as mmWave (Xiao et al. 2017). In each case, the bands have wavelengths up to a few millimeters, hence the name mmWave.

Relative to the sub-6 GHz microwave (μ Wave) frequencies used for many common applications, the mmWave bands offer several advantages. The larger bandwidths translate to higher capacity, the smaller wavelengths enable more (i.e., massive) antennas in same physical space, and the relatively closer spectral allocations lead to a more homogeneous propagation (Busari et al. 2017).

On the other hand, mmWave signals are prone to higher path loss, higher penetration loss, severe atmospheric absorption, higher susceptibility to shadowing and diffraction, more attenuation due to rain, and higher vulnerability to blockages by objects, as their wavelengths are typically less than the physical dimensions of the obstacles (Busari et al. 2017; Rappaport et al. 2013).

To counter the effects of the propagation losses, reduce interference, increase system throughput, and maximize network's energy efficiency, directional communication is mandatory for practical mmWave systems. Thus, beamforming can be employed to increase the antenna array gains, suppress interference, and improve the signal to noise ratio (SNR) of the links (Huang et al. 2018; Cui et al. 2018).

In addition, relay stations can be used to circumvent obstacles, thereby avoiding blockages and minimizing outages (Yang et al. 2018). More so, for the 50–200 m cell size envisaged for mmWave small cells (and other mmWave short-range applications), the expected attenuation (about 7 dB/km), due to heavy rainfalls, has minimal effect within such distances. Also, the high mmWave path loss limits inter-cell interference (ICI) and allows for more frequency reuse, which by extension improves the overall system capacity (Rappaport et al. 2013).

Historical Background

The study of mmWave predates the twentieth century. In the 1890s, scientists performed experiments at mmWave frequencies. However, mmWave channel measurements and system designs targeted at applications for radio communication started in the 1990s and early 2000s (Xiao et al. 2017). The spectrum crunch at μ Wave and the projected explosive traffic demands with the coming of fifth-generation (5G) networks and the Internet of Things (IoT)/Internet of Everything (IoE) have again motivated rigorous research and development (R&D) for mmWave systems and networks (Busari et al. 2017).

Foundations

MmWave channel measurement has received tremendous attention in recent years. Researchers in the academia and the industry have carried

out extensive mmWave measurement campaigns in different cities, countries, and continents of the world. A summary of mmWave channel measurements in the major cities of Europe, Asia, and the United States of America between 2012 and 2017 can be found in Xiao et al. (2017).

Since 2011, the New York University (NYU) WIRELESS researchers have been conducting extensive measurements at 28, 38, 60, and 73 GHz (Rappaport et al. 2013, 2015). The EU mmMAGIC project team also carried out mmWave measurements for mmWave frequencies 10–100 GHz (Jaeckel et al. 2014). Others include Zhao et al. at 32 GHz Zhao et al. (2017), Ai et al. at 26 GHz [8], METIS at 50–70 GHz (Ai et al. 2017), and the 5GCM at 6–100 GHz (Ghosh 2015), among others.

While most existing mmWave channel measurements were done for static radio channels, the world's first demonstration for the dynamic channel was carried out by Samsung at 28 GHz in 2014, reaching 1.2 Gbps transmission rate at 110 kmph. Contrary to earlier thoughts, this dynamic channel measurement points to the suitability of mmWave frequencies for mobile applications. It is also particularly useful to buttress the viability of mmWave small cells which typically do not involve high-velocity users (Mumtaz et al. 2017b).

For good mmWave channel measurements, the sounding equipment (both hardware and software) must have high performance and reliability. This is essential for the accuracy of the measurements and the corresponding models derived from them. High-frequency (mmWave) bands place high demands on the sounder components, as they must ensure wide frequency coverage, high dynamic range, and high output signal (in terms of power, stability, and quality) as well as guarantee the least possible distortion and harmonic content (Busari et al. 2017; Mumtaz et al. 2017b).

Efficient channel sounders must therefore be capable of measurements with operating frequencies up to several tens/hundreds of GHz and several GHz of mmWave bandwidth as well as multiple antennas at the transceivers. Similarly, sounding equipment should be capable of

measurements in static and dynamic conditions and indoor and outdoor environments. They should as well have capabilities for efficient signal generation, data acquisition, and storage. The equipment should also guarantee accurate synchronization, calibration, sensitivity, resolution, and flexibility for extension while maintaining reasonable system cost (Busari et al. 2017; Mumtaz et al. 2017b).

The extensive mmWave channel measurements have revealed marked differences in the propagation characteristics of mmWave relative to μ Wave. MmWave signals exhibit line-of-sight (LOS) or near-LOS propagation with absolute increase in path loss with increasing frequency, specular reflection attenuation, diffuse scattering, very high diffraction attenuation, and frequency dispersion effect, which, with the prospect of the huge bandwidth, allows the propagation to be considered as frequency-dependent. The mmWave signals also exhibit quasi-optical properties as the short wavelengths lead to weak diffractions. With highly directional mmWave communications, delay spreads of less than 20 ns are typical, and the number of scattering clusters becomes much less than at μ Wave (Rappaport et al. 2015; Xiao et al. 2017; Busari et al. 2017).

Under static conditions, mmWave channels exhibit frequency-selective fading which would need to be addressed by modulation or equalization. At mmWave frequencies, the assumption of asymptotic pair-wise orthogonality between channel vectors under independent and identically distributed (i.i.d) Rayleigh fading channel which is valid for μ Wave bands no longer holds. The number of independent multipath components (MPCs) becomes limited, and so channel vectors exhibit correlated fading. The channels are non-orthogonal and the waves are spherical. Spatial non-stationarity also becomes severe. Extensive indoor and outdoor channel measurement campaigns and simulations have been carried out by Rappaport et al. (2013), Rappaport et al. (2015), Jaeckel et al. (2014), Zhao et al. (2017), Ai et al. (2017), METIS (2015), and Ghosh (2015), among others, to deduce these outcomes.

Following the mmWave channel measurement activities, channel parameters (such as path loss, penetration loss, power delay profile (PDP), delay spread, shadowing, angular spreads, coherence bandwidth, etc.) are estimated from the obtained data or field results to develop channel models. Considering all necessary factors (such as frequency, propagation environment, scenario, etc.), the developed channel models provide statistical, mathematical, and analytical frameworks for simulation studies and performance evaluation of the communication systems. Such frameworks are also used to compare and/or validate empirical data from field deployment and operation tests (Mumtaz et al. 2017b).

Some of the general mmWave channel models that have resulted from mmWave measurement efforts include MiWEBA, COST 2100, QuaDRiGa, mmMAGIC, METIS, NYUSIM, 3GPP TR 38.900, 5GCM SIG, IMT-2020, and MG5GCM channel models, among others (3GPP 2016).

Key Applications

Due to the attractive capabilities and high commercial potentials of mmWave communications, spectrum allocation, regulatory, and standardization activities are being undertaken and rigorously pursued by relevant bodies such as the ITU, IEEE, ETSI, and the 3GPP. In fact, the 60 GHz mmWave WiFi (IEEE 802.11ad) that supports transmission rates up to 4–7 Gbps has already been standardized and has hit the market. It is expected to be followed by the 60 GHz mmWave IEEE 802.11ay capable of higher data rates up to 20–40 Gbps (Xiao et al. 2017).

5G mmWave cellular networks are also anticipated to be deployed by year 2020 to support many high data rate applications such as short-range communications, vehicular networks, and wireless in-band fronthauling/backhauling, among others. As a result, measurement campaigns, channel modeling, demos, prototyping, and field tests for mmWave technologies and applications have intensified. Standardization,

holistic deployment, performance evaluation, and business models will follow these efforts (Busari et al. 2017).

Future Directions

The mmWave channel is intrinsically an ultra-broadband channel with huge bandwidth and high spatial multiplexing capabilities to significantly enhance wireless access and improve cell and user throughputs. The mmWave spectrum has abundant available bandwidth (up to 270 GHz). With a reasonable assumption of 40% availability over time, the bands will possibly open up about 100 GHz new spectrum for different applications and services (such as cellular and fixed wireless communications) (Busari et al. 2017; Liu et al. 2018).

Since there is spectrum shortage at the congested sub-6 GHz μ Wave bands, relative to the explosive data rate demands projected for 2020 and beyond, mmWave wireless offers promising and exciting potentials to support next-generation systems. As a result, it features in the list of key enablers for the multi-gigabit-per-second (Gbps) wireless access for the fifth-generation (5G) and beyond-5G (B5G) mobile networks, as well as for high-rate wireless personal and local area networks (WPAN and WLAN) (Yang et al. 2018).

Though there are many challenges to address, the mmWave technology shows amazing prospects and potentials that will undoubtedly usher in a new era for services and applications not hitherto possible. Certainly, mmWave channel measurement is a critical component of the exciting journey.

Definition

Millimeter wave channel modeling is to use various deterministic or stochastic channel modeling approaches to describe the channel propagation characteristics at millimeter wave frequency bands and verify them by channel measurements.

Historical Background

Channel modeling is important for wireless communication system design, test, and performance

evaluation. It has been the foundation of wireless communications for years. As wireless communication systems evolve from the first generation (1G) to the forthcoming fifth generation (5G), many channel models have been proposed, among which the series of COST-, WINNER-, and 3GPP-family models are the most widely investigated ones. The description of wireless channels has also evolved from time domain to time, delay, and spatial domains. Another obvious distinction between different generations of wireless communication systems lies in the carrier frequency.

Due to the congestion of sub-6 GHz bands, millimeter wave (mmWave) technology has been proposed as a key technology for 5G to enable high data rate transmissions (Wang et al. 2014). In general, it denotes the frequency range of 30–300 GHz, but sometimes 10–30 GHz bands are also included as they share some similar propagation characteristics (Huang et al. 2017). MmWave channel measurements and modeling have drawn much attention since T. S. Rappaport's breakthrough work in Rappaport (1991). It demonstrated that mmWave can work for 5G mobile cellular networks.

In the early stage, research of mmWave concentrated on 60 GHz bands as there are at least 5 GHz bandwidths worldwide (Wu et al. 2017a). Recently, other frequency bands such as 11, 15, 26, 28, 32, 38, and 73 GHz have widely been investigated (Rappaport et al. 2015). Various channel measurements and models at these frequency bands have pushed the application of mmWave communications to 5G wireless networks.

Moreover, channel models are required for simulating propagation in a reproducible and cost-effective way and are used to accurately design and compare radio air interfaces and system deployments. Common wireless channel model parameters include carrier frequency, bandwidth, two-dimensional (2-D) or three-dimensional

(3-D) distance between the transmitter (Tx) and receiver (Rx), Doppler effects, delays, and angles. The definitive challenge for a 5G channel model is to provide a fundamental physical basis while

being flexible and accurate, especially across a wide frequency range such as 0.5–100 GHz. Recently, a lot of research works aiming at understanding the propagation mechanisms and channel behavior at the frequency bands above 6GHz have been published.

Foundations

For mmWave channel modeling, some fundamental knowledge will be useful. MmWave frequency allocations, propagation characterizations, channel model standardizations, channel modeling methods, and proposed mmWave channel models will be discussed here.

Frequency Allocations

The 57–64 GHz band was allocated in North America and Korea. In Japan, Europe, China, and Australia, the 59–66, 57–66, 59–64, and 59.4–62.9 GHz bands were allocated, respectively. At the World Radio Communication Conference 2015 (WRC-15), 11 frequency bands between 24.25 GHz and 86 GHz are allocated for 5G by ITU. The 24.25–27.5, 37–40.5, 42.5–43.5, 45.5–47, 47.2–50.2, 50.4–52.6, 66–76, and 81–86 GHz bands were allocated, and the 31.8–33.4, 40.5–42.5, and 47–47.2 GHz bands require additional allocations. Those frequency allocations have accelerated the developments of mmWave communications around the world.

In the United States, the 27.5–28.35 (28), 37–38.6 (37), 38.6–40 (39), and 64–71 GHz bands were allocated for flexible wireless use. Additional allocated bands include 24.25–24.45, 24.75–25.25 (24), and 47.2–48.2 GHz. Europe limits its considerations to the bands listed by WRC-15, in particular the 24.25–27.5 (26), 31.8–33.4 (32), and 40.5–43.5 GHz bands. In Korea, the 26.5–29.5 GHz (28 GHz) band was allocated. In Japan, the 27.5–29.5GHz (28 GHz) band was allocated in accordance with America and Korea. In China, the focused bands are 24.25–27.5 GHz (26GHz) and 37–43.5 GHz bands.

Propagation Characterizations

MmWave has some unique propagation characteristics, which should be carefully studied (Hemadep et al. 2018). MmWave has high path loss and high penetration loss, especially for outdoor-to-indoor (O2I) scenarios. Atmospheric attenuation becomes severe at mmWave bands. The attenuation caused by oxygen absorption can be 15 dB/km and 1.4 dB/km for 60 GHz and 120 GHz, respectively. For water vapor, the attenuation would be 0.18 dB/km and 28.35 dB/km at 23 GHz and 183 GHz, respectively. Rain can also cause 2.55–20 dB/km attenuation depending on the rainfall rate. Foliage also adds additional attenuation. As the size of many objects is at the level of the wavelength, diffraction becomes an important propagation mechanism, and the first Fresnel zone is narrow. The channel also shows sparsity in spatial domain. Blockage caused by human movement in indoor scenarios and buildings in outdoor scenarios will make the line-of-sight (LOS) component unfeasible, thus changing the channel from LOS to non-LOS (NLOS) scenarios (Qi et al. 2017).

Channel Model Standardizations

Several standards have dedicated to 60 GHz bands. IEEE 802.15.3c and 802.11ad have been developed for wireless personal area network (WPAN) in March 2007 and wireless local area network (WLAN) in May 2010, respectively, while 802.11ay is being developed for next-generation wireless fidelity (WiFi). MiWEBA channel model was released in June 2014 for 60 GHz (57–66 GHz) outdoor scenarios, including open area (campus), street canyon, hotel lobby, fronthaul/backhaul, and device-to-device (D2D).

The METIS channel model was released in February 2015. It can support up to 86 GHz with high bandwidth. Supported scenarios include dense urban, urban, rural, indoor (office and shopping mall), and highway.

The mmMAGIC channel model was released in May 2017. Its frequency range is from 6 GHz to 100 GHz. Supported scenarios include urban micro (UMi) (street canyon and open square),

indoor (office, shopping mall, and airport), O2I, stadium, and metro station.

The 5GCM white paper was first released in December 2015 in IEEE Globecom'15 and updated in October 2016. It intends to develop channel models for frequency bands up to 100 GHz using the geometry-based stochastic channel modeling (GBSM) approach and has conducted many channel measurements in various scenarios including UMi, urban macro (UMa), and indoor. The majority of the modeling ideas and parameter values were adopted in 3GPP TR 38.900 named “Study on Channel Model for Frequency Spectrum Above 6 GHz”, which was first released in February 2016 and updated in July 2017. Its alternative version is 3GPP TR 38.901 named “Study on Channel Model for Frequencies From 0.5 to 100 GHz”, in which the sub-6 GHz bands are also covered. It was first released in February 2017 and updated in December 2017.

Channel Modeling Methods

In general, channel modeling methods can be classified into deterministic and stochastic ones or the combination of them (Yang et al. 2017). Deterministic channel models are site-specific and can be verified by comparison of detailed path parameters with channel measurements. Stochastic channel models aim to model general environments and can be verified by comparison of channel statistical properties with channel measurements.

Deterministic channel models include ray tracing model, map-based model, and point cloud model. Ray tracing is based on geometry optics (GO), geometrical theory of diffraction (GTD), and uniform theory of diffraction (UTD), which are approximation and simplification of high-frequency electromagnetic propagations mechanisms. The METIS map-based model is based on ray tracing using a simplified geometric description of the environment. Point cloud is a ray tracing-like prediction tool to characterize the environment with higher precision (Järveläinen et al. 2016). Quasi-deterministic (Q-D) model, which is adopted by MiWEBA and IEEE 802.11ay, is a semi-deterministic channel model.

Stochastic channel models include SV-based model, propagation graph model, and GBSM. SV-based model assumes rays arrive in clusters and is used in IEEE 802.15.3c and 802.11ad models. Propagation graph model is based on graph theory. It models Tx, Rx, and scatterers as vertices and propagation paths as edges. GBSM has widely been used for channel modeling and adopted in many standard channel models like WINNER, 3GPP TR 38.900/901, NYU WIRELESS, mmMAGIC QuaDRiGa, and METIS stochastic models.

Proposed mmWave Channel Models

In order to meet the requirements of mmWave channel models, many major organizations, such as 3GPP, METIS, mmMAGIC, and 5GCM, have proposed the models for LOS probability, path loss, and building penetration. In the LOS probability model, the LOS probability is often modeled as a function of the 2-D distance between the Tx and Rx, and it includes UMi LOS probability, UMa LOS probability, and InH LoS probability. Furthermore, the large-scale path loss and O2I penetration loss models were also proposed in Rappaport et al. (2017).

Key Applications

As we know, 5G will be used in three scenarios, i.e., enhanced mobile broadband (eMBB), massive machine-type communications (mMTC), and ultrareliable low-latency communications (uRLLC). MmWave will be a key technology to enable these applications. Typical and potential application scenarios include fronthaul/backhaul, indoor hotspots, cellular networks, high-speed train (HST), vehicle-to-vehicle (V2V), D2D, unmanned aerial vehicle (UAV) communications, etc.

Future Directions

mmWave Channel Measurements in New Scenarios

As mmWave will be applied to various new scenarios, channel measurement campaigns in

these challenging scenarios are indispensable, which include but are not limited to massive multiple-input multiple-output (MIMO) (Busari et al. 2017), HST, V2V, D2D, UAV communications, etc. MmWave channel measurements in these new scenarios will lead to a better understanding of mmWave propagation characteristics and more accurate mmWave channel models.

General 5G Channel Models

Though many channel models have been proposed, most of them cannot fulfill all the requirements of 5G, covering the vast mmWave frequency bands and new propagation characteristics. A preliminary general 5G channel model was proposed in Wu et al. (2017b). It aimed at capturing small-scale fading channel characteristics of key 5G communication scenarios, such as massive MIMO, HST, V2V, and mmWave. It will serve as a good guideline for future more general and standard 5G models.

Big Data-Enabled mmWave Channel Modeling

Wireless big data has now been investigated both in academia and industry to handle massive datasets generated in wireless networks using artificial intelligence (AI) technologies and machine learning (ML) algorithms (Bi et al. 2015). Big data analytics have been applied to different layers of wireless networks for channel estimation, positioning/localization, network optimization and management, etc. Some preliminary works also apply big data analytics to wireless channel modeling (Ma et al. 2017). Big data will be a powerful tool for mmWave channel modeling by training and learning big channel measurement or simulation datasets.

Medium access control in millimeter-wave wireless communications

Definition

The millimeter-wave (mmWave) medium access control (MAC) is a set of routines that regulate access to a common wireless communications medium in the mmWave frequency bands. MAC layer is part of layer 2 of the OSI model (Bertsekas and Gallager 1992). The primary functions of this layer for mmWave wireless communications are the following:

- Data encapsulation, including the frame assembly and error control;
- Media access control, including initial frame transmission, retransmission in the case of failure, and flow control; and
- Initial access, mobility management, and handover.

The first two items are common to MAC of any communication systems, and the last one is more specific for mmWave networks.

The choice of MAC protocol directly influences most performance measures, including

end-to-end latency, network throughput, reliability, and energy efficiency, among others.

Historical Background

Millimeter-wave communications use the part of the electromagnetic spectrum in the range 30–300 GHz, which corresponds to wavelengths from 10 to 1 mm. In the literature, however, mmWave frequencies casually refer to the frequency band between 6 and 300 GHz. The mmWave wireless communications exhibit the following fundamental physical characteristics: short wavelengths, large bandwidth, severe propagation loss, high attenuation through most solid materials, sparse scattering environments, and large-scale antennas (Rappaport et al. 2013). The special characteristics of mmWave systems demand a thorough reconsideration of traditional protocol design principles, especially at the MAC layer with respect to the MAC protocols of traditional wireless communications.

When sending data over a network, the MAC layer encapsulates its incoming payload (data frames from higher layers) into frames appropriate for the transmission medium, adds a frame check sequence to identify transmission errors, and then forwards the data to the physical layer after running a multiple access procedure (Bertsekas and Gallager 1992). This procedure is necessary to resolve or avoid collisions, retransmit the collided or lost frames, and control the transmission rate. At the receiver side, the MAC layer verifies the sender's frame check sequences, removes preambles and frame headers, and delivers the payload to the higher layers (Bertsekas and Gallager 1992). In wireless networks, the design of the MAC layer is tightly integrated with the design of the physical layer. The multiple access protocol of short-range wireless networks (such as wireless personal and local area networks) may rely on carrier sensing among devices and multihop communications. The multiple access protocols of the cellular networks, like Long-Term Evolution (LTE), are usually optimized and run by the base stations (3GPP TS 36.321 2017).

At the mmWave frequency band, there are several standardization activities within cellular networks, wireless personal area networks (WPANs), and wireless local area networks (WLANs), such as 3GPP NR 3GPP TS 38.321 (2017), IEEE 802.15.3 Task Group 3c (TG3c) (IEEE 802.15.3c 2009), IEEE 802.11ad standardization task group (IEEE 802.11ad 2012), WirelessHD Consortium, and Wireless Gigabit Alliance (WiGig). The existing established standards are very suboptimal, and efficient MAC layer design for mmWave networks is a topic of intense research. Ghadikolaei et al. (2015) and Ghadikolaei et al. (2016) discussed the main MAC layer issues of infrastructure-based (e.g., cellular) and infrastructure-free (e.g., ad hoc) mmWave networks, respectively. For short-range networks, IEEE 802.11ay is the most recent study group within IEEE, formed in May 2015, which aims to modify IEEE 802.11ad to enhance the throughput, range, and most importantly the use cases, while ensuring backward compatibility and coexistence with legacy mmWave standards. Broadly speaking, IEEE standards define a network with one coordinator and several mmWave devices. The coordinator, which can be a device itself, is responsible for broadcasting, synchronization beacons, running initial access beacons, and managing radio resources. Figure 1 illustrates generic timing segmentation of IEEE 802.15.3c and IEEE 802.11ad.

The IEEE 802.15.3c MAC procedure was standardized in 2009 (IEEE 802.15.3c 2009). It selects one device, among a group of devices in the network, as the piconet coordinator (PNC), broadcasting beacon messages. Time is divided into successive super-frames, each consisting of three portions, beacon, contention access period (CAP), and channel time allocation period (CTAP), as shown in Fig. 1a. In the beacon, the coordinator transmits omnidirectional or multiple quasi-omnidirectional beacons to facilitate the device discovery procedure. In the CAP, devices with low QoS requirements start their data transmissions. Devices with high QoS requirements contend to register their channel access requests at the PNC, based on carrier

Millimeter Wave MAC Layer, Fig. 1 Network timing structure of existing IEEE mmWave standards. In IEEE 802.15.3c, beacon messages are transmitted in the Beacon phase. Channel access requests are made in CAP and served in CTAP using TDMA. Similar procedures are adopted in IEEE 802.11ad. (This picture is reproduced from Ghadikolaei et al. 2016). Millimeter Wave MAC Layer, Table 1 Application scenarios for short-/medium-range mmWave networks. This table is deduced from ongoing discussions inside IEEE 802.11ay study group. “NS” means not specified yet

Usage models	Delay (s)	Availability	Range (m)	Rate (Gbps)	Application scenarios
Ultrashort-range communications	<1	NS	<10	10	Wireless tollgate to transfer e-magazine, picture library, 4K movie trailers, 4K movies
8K Video transfer at smart home	<0.005	NS	<5	28	8K video stream between a source device (e.g., setup box) and a sink device (e.g. smart TV), replacement of wired interface
Augmented reality	<0.005	NS	<10	20	Interface between a mobile wearable device and its managing device to deliver 3D video
Data center	<0.1	99.99%	<5	40	Inter-rack connectivity
Vehicular networks	<0.1	NS	<1000	ns	Intra- and inter-car connectivity, intersection collision avoidance, public safety
Video on-demand	<0.1	NS	<100	NS	Broadcast in crowd public places (e.g., classroom, in flight, train, bus, exhibitions)
Mobile offloading	<0.1	99.99%	<100	20	Offload video traffic from cellular interface to the mmWave interface
Mobile fronthauling	<0.035	99.99%	<200	20	Wireless connections between remote radio heads and base band unit
Mobile backhauling	<0.035	99.99%	<1000	20	Small cell backhauling, multihop backhauling, inter-building communications

sense multiple access with collision avoidance (CSMA/CA). The PNC serves the registered devices during CTAP. Resource allocation in CTAP is based on time division multiple access (TDMA), in which dedicated channel time allocations (CTAs) are used for different data traffic.

The IEEE 802.11ad was standardized in 2012. It adds modifications to the IEEE 802.11 physical and MAC layers to enable mmWave communications at 60 GHz (IEEE 802.11ad 2012). It defines a network as a personal basic ser-

vice set (PBSS) with one coordinator, called PBSS control point (PCP), and several stations. A super-frame, called beacon interval, is divided into a beacon header interval (BHI) and a data transfer interval (DTI); see Fig. 1b. BHI consists of a beacon transmission interval (BTI), an association beamforming training (A-BFT), and an announcement transmission interval (ATI). DTI consists of several contention-based access periods (CBAPs) and service periods (SPs). In BTI, PCP transmits directional beacon frames that contain basic timing for the personal BSS, fol-

lowed by beamforming training and association to PCP in the A-BFT period. ATI is allocated for request-response services where PCP sends information to the stations. Depending on the required QoS level, a device will be scheduled in the CBAP to transmit data using CSMA/CA or in the SP for contention-free access using TDMA. This schedule is announced to the participating stations prior to the start of DTI.

Key Applications

Currently, the mmWave spectrum is primarily used for satellite communications, long-range point-to-point communications, military applications, and local multipoint distribution service (Rappaport et al. 2014). There are growing interests in using mmWave systems to support extremely high data rate and low latency services for short- and medium-range networks. Table 1 shows some of these potential use cases.

Definition

Millimeter wave massive multiple-input multiple-output (MIMO) is a wireless communication technique that transmits and receives millimeter-length electromagnetic wave signals through massive antenna arrays at transmitters and receivers. Multiantenna arrays in MIMO enable simultaneous transmissions of multiple data

streams through wireless channels. In most cases, massive MIMO implicitly implies that multiple users are served simultaneously, that is, a multiuser massive MIMO. If only the transmitter deploys a multiantenna array while each receiver equips a single antenna, the terminology MIMO refers to, more formally, multiple-input single-output (MISO). If only the receiver deploys an antenna array while the transmitter equips a single antenna, the terminology MIMO refers to, more formally, single-input multiple-output (SIMO). In literature, millimeter wave massive MIMO can also represent millimeter wave massive MISO or millimeter wave massive SIMO communications.

Historical Background

The development of millimeter wave massive MIMO traces back to a natural combination of two lines of technology evolutions, i.e., millimeter wave communication and massive MIMO, in wireless communication. Millimeter wave refers to the radio spectrum with wavelength between 1 and 10 mm, corresponding to the spectrum between 30 and 300 GHz that is sometimes called the extremely high frequency (EHF) range. Millimeter wave communication was firstly experimented by J. C. Bose in 1895 realizing transmission and reception of electromagnetic waves at 60 GHz over 23 m distance (Emerson 1997). Early applications, however, emerged in radio astronomy and military nearly half a century later. Commercial applications of millimeter wave radar and communication devices started to become popular with the development of millimeter wave integrated circuits after the 1980s. Communications in millimeter wave usually operate with a much larger bandwidth that can be tens of times of the available bandwidth for wireless communications in microwave, which is able to support very high data rate communications. On the other hand, attenuation of radio waves increases exponentially in both propagation distance and the radio frequency. Millimeter wave communications thus face the challenge of high

propagation loss due to the high frequency. Moreover, compared to microwave propagation, attenuation of millimeter wave propagation also depends heavily on many other factors, e.g., atmospheric humidity, fog, and rain. Studies were conducted in investigating propagation characteristics of millimeter waves for communication system design (Rappaport et al. 2013). In 2013, millimeter wave communication was specified in the Wi-Fi standard IEEE 802.11ad in the 60 GHz spectrum to achieve high data rate transmission up to 7 Gbit/s (Wi-Fi Alliance 2016).

The invention of MIMO in wireless communication traces back to the early 1990s. The well-known MIMO transmission strategy, named BLAST, was firstly reported in Foschini (1996). Theoretical channel capacity of the MIMO channel was analyzed in Foschini and Gans (1998) in 1998. It revealed that MIMO is able to boost the channel capacity multiple times by deploying multiantenna arrays at both transmitter and receiver. Commercial applications of MIMO were successful in both Wi-Fi and 3G/4G cellular networks, e.g., by standardizing multiantenna stations and terminals with multiple antennas up to eight.

In 2010, a milestone in the development of MIMO technology was the initial introduction of massive MIMO by Dr. T. Marzetta from Bell lab (Marzetta 2010). Massive MIMO proposes to equip the device with an antenna array using a very large number of antenna elements, which is able to support many users to transmit data simultaneously and efficiently without interfering each other too much. The study in Ngo et al. (2013) discovered that the transmit power can be effectively scaled down with the number of antennas while still guaranteeing a desired transmission rate in massive MIMO. Due to its advantages, massive MIMO has been recognized as one of the most essential technology evolutions in the next-generation cellular network, namely 5G. With the deployment of a massive antenna array, however, implementation of massive MIMO in practice also faces many challenges. For instance, estimation of the large-dimensional MIMO channel is resource-hungry; deployment of a massive antenna array occupies a huge space when using

microwave spectrum; and the cost of constructing and driving a massive antenna array could be expensive (Rusek et al. 2013).

Millimeter wave massive MIMO, more than a natural combination of massive MIMO communication with millimeter wave spectrum, exhibits multiple unique features compared to conventional massive MIMO using the microwave spectrum. Besides the large amount of spectrum resource at millimeter wave band, the much shorter wavelength facilitates packing massive antennas into an array of compact size, which endues millimeter wave massive MIMO with great potential in providing ultra-high data rate communications (Xiao et al. 2017). Because millimeter wave channels are sparse in propagation paths and suffer large path-loss and blockage, the MIMO transmission and reception design of millimeter massive MIMO is substantially different from that for conventional microwave massive MIMO. In order to combat the large path-loss, power efficiency has been one of the principle considerations in system design. It becomes particularly important to form directional beams in millimeter wave MIMO by using massive antenna array (Huang et al. 2018). Transmit power can thus be mostly assembled in the directional and narrow beams to combat large path-loss and enhance communication links.

Understanding propagation characteristics of millimeter wave massive MIMO channels is crucial for both optimization of antenna array topology and design of directional beam patterns. A thorough survey was reported in Rappaport et al. (2017) on existing measurement results and modeling of millimeter wave MIMO propagations, especially in the context of their applications in 5G. A common agreement is that the channel is sparse in the angular domain, and in a large portion of application scenarios, line-of-sight propagation components play a significant part of all propagation effects. The sparsity nature, in one way, provides great potential in solving the channel estimation challenge in massive MIMO, while in the other way it limits the number of degree of freedoms (DoF) that can be achieved through the large dimensional MIMO channel.

In recent years, new signal processing techniques (Heath et al. 2016) as well as hardware-friendly architectures (Liang et al. 2014; Ayach et al. 2014) are emerging to exploit these unique features and meet corresponding challenges in millimeter wave massive MIMO. One of the well-acknowledged new solutions refers to as hybrid analog-digital precoding/combining that balances the sparsity channel feature and hardware constraints in millimeter wave MIMO circuit design (Brady et al. 2013; He et al. 2017). Design parameters in hybrid analog-digital millimeter wave massive MIMO system were analyzed in Xu et al. (2017) and Xue et al. (2017), proposing an effective DoF in performance characterization (Xue et al. 2017). Another design trend is to replace high-resolution analog-to-digital converters (ADC) in conventional massive MIMO by low-resolution ADCs in order to achieve reduction in both circuit power consumption and hardware cost for implementations. Studies, e.g., (Liu et al. 2016; Saxena et al. 2017), discovered that low-resolution ADCs cause negligible performance loss compensable by a massive antenna array in millimeter wave communications.

Key Applications

Millimeter wave massive MIMO enables ultra-high data rate communications in applications like wireless backhaul and ultra-dense small cell coverage in cellular networks. It is also becoming a highly attractive solution for realizing low latency and/or wideband communications in unmanned aerial vehicular communications and the coming intelligent vehicular communication networks (Xiao et al. 2016). Vehicular radar communication and detection is also a growing application of millimeter wave massive MIMO.

Multiple access in high frequency

Definitions

Millimeter-wave NOMA refers to using non-orthogonal multiple access (NOMA) in millimeter-wave frequencies. On the one hand, millimeter-wave communications, operating from 30 to 300 GHz, provide an opportunity to meet explosive capacity demand for wireless

communications. On the other hand, multiple access technologies are necessary for supporting multiple users in wireless communication systems. Particularly, NOMA can significantly improve the spectral efficiency and connectivity density. In contrast to the conventional orthogonal multiple access (OMA) schemes realized in the time-, frequency-, code-domain or their combinations, NOMA can be realized in a new domain, i.e., the power domain. By performing superposition coding at the transmitter and successive interference cancellation (SIC) at the receiver, multiple users can be simultaneously supported at the same time-frequency-space resources, and the channel gain difference among users can be translated into multiplexing gain by superposition coding. By integrating NOMA into millimeter-wave communications, potential performance gain can be achieved.

Key Points

Multiple access technologies are necessary for supporting multiple users in mobile networks, and they have been widely investigated in the lower frequency bands. Different multiple access technologies have been utilized in practical systems, including frequency division multiple access (FDMA), time division multiple access (TDMA), code division multiple access (CDMA), and orthogonal frequency division multiple access (OFDMA). These multiple access technologies are also applicable to millimeter-wave band, but in different flavors than in lower frequency bands due to the increased complexity caused by the greatly increased bandwidth, and the different channel characteristics in millimeter-wave bands, e.g., highly directional transmissions (Mumtaz et al. 2016).

In addition to orders-of-magnitude larger bandwidths, the smaller wavelengths at millimeter-wave allow more antennas in a same physical space, which enables massive multiple input multiple output (MIMO) to provide more multiplexing gain and beamforming gain (Swindlehurst et al. 2014). In fact, beamforming

with a large antenna array is a key characteristic of millimeter-wave communication, which is used to compensate for the high pass loss of millimeter-wave signals (Xiao et al. 2017a).

To further increase the spectral efficiency, NOMA has been recently considered in millimeter-wave communications. It has been shown that NOMA can significantly improve the spectral efficiency compared to the conventional OMA schemes (Dai et al. 2015). In Ding et al. (2017), the integration of NOMA with millimeter-wave communications has been investigated, where random steering single-beamforming was adopted, which can work only in a special case that the NOMA users are close to each other. In Xiao et al. (2017b), joint power allocation and beamforming to maximize the sum rate of a two-user millimeter-wave NOMA system was proposed, where an analog beamforming structure with a phased array was considered.

Furthermore, it is well known that in conventional MIMO systems, each antenna usually requires one dedicated radio-frequency (RF) chain to realize the fully digital signal processing (Rusek et al. 2013). In this way, the use of a very large number of antennas in millimeter-wave massive MIMO systems leads to an equally large number of RF chains, which will result in unaffordable hardware cost and energy consumption (Heath et al. 2016). To address this issue, hybrid precoding (HP) has been proposed to significantly reduce the number of required RF chains in millimeter-wave massive MIMO systems without an obvious performance loss (Rusek et al. 2013).

By using NOMA in HP-based millimeter-wave massive MIMO systems, more than one user can be supported in each beam with the aid of intra-beam superposition coding and SIC, which is essentially different from conventional millimeter-wave massive MIMO using one beam to serve only one user at the same time-frequency resources. Particularly, NOMA was applied to beamspace MIMO for the first time in Wang et al. (2017), which can be regarded as a low-complexity realization of HP, and power allocation was optimized to maximize

the achievable sum rate. In addition, NOMA was also utilized in fully connected HP architecture in Yuan et al. (2017), and digital precoding was designed by modifying the conventional block diagonalization (BD) precoding scheme. Furthermore, a more sophisticated digital precoding design, i.e., minorization-maximization (MM)-based precoding, was proposed in Zhao et al. (2017) to maximize the achievable sum rate. Besides, power allocation was optimized in Hao et al. (2017) to maximize the energy efficiency of millimeter-wave massive MIMO-NOMA systems, and an iterative algorithm was proposed to obtain the optimal power allocation.

Note that the highly direction feature of millimeter-wave propagation makes the users' channels (along the same or similar direction) highly correlated, which facilitates the integration of NOMA in millimeter-wave communication. Therefore, considering the harmony between the millimeter-wave channel characteristics and the principle of NOMA, the use of NOMA for millimeter-wave communications is a very promising research direction deserves further investigations.

Synonyms

[Millimeter Wave Communication Security](#); [Millimeter Wave Physical Layer Security](#)

Definition

Different from the traditional communication security methods which provide data security by cryptographic techniques, physical layer security methods guarantee secure wireless transmissions by exploiting the imperfections of the communications medium (Yang et al. 2015). With physical layer security methods, communication security can be achieved by degrading the quality of signal reception at potential eavesdroppers and therefore preventing them from acquiring confidential information from the received signal. However, compared to microwave communications, severe path loss in millimeter wave (mmWave) makes it hard to support long-distance transmissions. Thanks to the short wavelength of mmWave, it is possible to employ a large number of antennas in a small size terminal. With the help of the large number of antennas, directional beamforming and multiple-antenna technologies, etc. become the powerful tools for achieving long-distance communications and enhancing the physical layer security in mmWave networks. With the degrees of freedom provided by multiple antennas (Wang and Wang 2016), better communication security can be achieved in mmWave communications.

Key Points

The conventional communication security can be achieved by ensuring all involved entities load proper and authenticated cryptographic information. However, the physical layer security does not consider about how those security protocols are executed and does not require to implement any extra security schemes or algorithms on other layers above the physical layer (Liu et al. 2017). There are many techniques that can be used for improving the security of mmWave, such as directional transmission, antenna subset modulation, and directional modulation.

Directional Transmission: Different from microwave networks, directional transmission

techniques should be used in mmWave networks to achieve better performance. Thus, the signal or interference power in mmWave communications is highly directional and closely related to critical parameters, such as transmission distance, transmit power, offset angle of departure/arrival, and beamwidth. They all have impact on the performance of mmWave communications due to the inherent directivity. If one or more of these parameters do not reach the predefined thresholds, the directional communication in mmWave networks will be damaged. Therefore, it is hard for eavesdroppers to acquire confidential information from the received signal. Meanwhile, physical layer security could naturally gain the benefit from the directivity.

Antenna Subset Modulation: With multi-antenna techniques, by using random antenna subsets and performing analog precoding with antenna selection, instead of using all antennas for beamforming, a random set of antennas are co-phased to transmit the information symbol to the desired receiver, while the rest of the antennas are used to randomize the far field radiation pattern at non-desired receiver directions. The indices of these antennas are randomized in every symbol transmission. Thus, coherent transmission to the desired receiver and a noise-like signal that jams potential eavesdroppers can be achieved (Eltayeb et al. 2017). Similarly, another antenna subset modulation method to realize physical layer security of mmWave is to modulate the radiation pattern at the symbol rate by driving only a subset of antennas in the array. This results in a directional radiation pattern that projects a sharply defined constellation in the desired direction and expanded further randomized constellation in other directions (Valliappan et al. 2013). The way to implement antenna subset modulation is randomly selecting an antenna subset for every symbol. The symbol modulation for a desired receiver along the main lobe will not be affected by randomly switching antenna subsets.

Directional Modulation: Several directional modulation approaches have been proposed that leverage multiple transmit antennas including near field antenna-level modulation,

switched antenna phased array transmitters, and spatial keying transmission techniques such as spatial modulation and space shift keying to achieve enhanced security (Valliappan et al. 2013). A hybrid multiple-input multiple-output (MIMO) phased array time-modulated directional modulation scheme was proposed to improve the physical layer security of mmWave communications (Wang and Zheng 2018). Because the hybrid MIMO phased array can take advantage of the spatial diversity of MIMO, the main advantage of phased array in coherent directional gain will not be sacrificed. Then, the transmit antenna arrays will be divided into multiple subarrays, and each subarray can be used to form a directional beam. All subarrays are jointly combined to work as an MIMO for higher angular resolution or multiuser communications. Therefore, even the eavesdropper's position is unknown, physical layer security can also be realized by applying a time-modulated directional modulation scheme.

In addition, heterogeneous networks (Het-Nets) architecture has attracted a lot of research interests recently. To provide physical layer security in the new HetNet architecture, dense small cells are deployed to bring ubiquitous inter-tier and intra-tier interference (Zhu et al. 2017). Such interference can be utilized for confounding the eavesdroppers and achieving secure communications at the physical layer as mentioned in *antenna subset modulation*.

We can see from the above physical layer security methods that they do not rely on upper-layer data encryption or secret keys. Thus, the processing overhead and additional communication overhead can be reduced. Physical layer security of mmWave communications is a promising research topic for mmWave security.

Key Applications

In order to provide ultrahigh-speed wireless transmissions for future communication systems,

mmWave will play an important role in wireless local area networks (WLANs), fifth generation (5G) mobile communication system, vehicular communication system, and so on. With the increasing demand of privacy and security of every user, communication security is critical to all the above communication systems. mmWave security technologies can be used in any mmWave networks to provide the desired users secure communications and prevent the information from being obtained by potential eavesdroppers.

High-frequency MIMO; Millimeter-wave massive MIMO

Definitions

Multiple-input multiple-output (MIMO) is a technique that employs multiple transmit and receive antennas to send and receive more than one data stream simultaneously over the same time/frequency resource. Millimeter-wave (mmWave) MIMO is the MIMO technique operated at mmWave frequencies (i.e., 30–300 GHz).

Historical Background

The history of MIMO can be traced back to 1993, when Arogyaswami Paulraj and Thomas Kailath proposed to “split a high-rate signal into several low-rate signals to be transmitted from spatially separated transmitters and recovered by

the receive antenna array based on differences in directions-of-arrival” (Li et al. 2010). After that, this technique has attracted great interest from both the academic and industry communities and obtained a huge development. Currently, MIMO technique has been widely used in wireless communication systems working at sub-6 GHz frequencies, such as 4G cellular systems (Li et al. 2010). By employing multiple antennas, MIMO can achieve multiplexing gain with reduced interference to improve the spectrum efficiency.

However, the MIMO technique in current 4G cellular systems only employs a small number of transmit antennas and receive antennas due to the limited physical space at the transmitter and receiver. As a result, the improvement in the spectrum efficiency is still limited, which cannot meet the one thousand times increase in data traffic predicted for further 5G cellular systems (Mumtaz et al. 2016). To solve this problem, one possible way is to extend the MIMO technique at sub-6 GHz frequencies to mmWave frequencies (Mumtaz et al. 2016). On one hand, mmWave band can provide more than 2 GHz bandwidth for communication, which is much wider than the 20 MHz bandwidth in current 4G cellular systems. On the other hand, the short wavelengths associated with mmWave frequencies enable a large antenna array to be packed in a small physical space, which means that MIMO with a large antenna array can be easily employed at mmWave frequencies to considerably improve the spectrum efficiency.

Foundations

The mmWave MIMO technique will be quite different from the one at sub-6 GHz frequencies due to the different channel characteristics and additional hardware constraints found at mmWave frequencies (Gao et al. 2018). The conventional MIMO architecture is fully digital as shown in Fig. 1a, where each antenna requires one dedicated RF chain (including power amplifier, low-noise amplifier, data converter, mixer, and so on) to perform digital signal processing in the baseband (Li et al. 2010). For mmWave MIMO,

Millimeter-Wave (mmWave) Multiple-Input Multiple-Output (MIMO) Technique, Fig. 1 MIMO architectures: (a) fully digital architecture; (b) hybrid analog and digital architecture

this architecture will suffer from unaffordable hardware cost and power consumption, since (1) the number of antennas is usually large due to the short wavelengths (e.g., 256 antennas at mmWave frequencies instead of 8 antennas at sub-6 GHz frequencies) (Mumtaz et al. 2016) and (2) the power consumption of RF chain is high due to the increased sampling rate (e.g., 250 mW/RF chain at mmWave frequencies, compared with 30 mW/RF chain at sub-6 GHz frequencies) (Gao et al. 2018).

To this end, the hybrid analog and digital architecture is proposed for mmWave MIMO (Gao et al. 2018), as shown in Fig. 1b. This architecture divides the conventional digital signal processing of large size into two parts, i.e., a large-size analog signal processing (realized by analog circuit) and a dimension-reduced digital signal processing (requiring a small number of RF chains). The smallest number of required RF chains in hybrid architecture can equal the number of data streams for communication, which is usually much smaller than the number of antennas. In this way, the number of RF chains can be significantly reduced, leading to quite low energy consumption. On the other hand, due to the limited number of effective scatterers at mmWave frequencies, the mmWave MIMO channel matrix is usually low-rank (Gao et al. 2018), and the maximum number of data streams that can be simultaneously transmitted in such low-rank channel is small. Therefore,

as long as the number of RF chains is larger than the rank of channel matrix, the dimension-reduced digital signal processing is still able to fully achieve the multiplexing gain. As a result, hybrid architecture can achieve a better trade-off between the hardware cost/energy consumption and the sum-rate performance (Gao et al. 2018).

Architecture for mmWave MIMO

The analog circuit of mmWave MIMO with hybrid architecture can be implemented by different hardware networks (Gao et al. 2018; Méndez-Rial et al. 2016) as listed below.

- (N1) *Fully connected network with phase shifters*: In this network, each RF chain is connected to all antennas via phase shifters, as shown in Fig. 2a. For each RF chain, full array gain can be achieved by adjusting the phases of transmitted signals on all antennas to provide high array gain. By employing such network, all elements of the analog precoder/combiner have the same fixed amplitude.
- (N2) *Sub-connected network with phase shifters*: In this network, each RF chain is only connected to a sub-antenna array via phase shifters, as shown in Fig. 2b. Due to this limitation, for each RF chain, only the transmitted signals on a subset

of antennas can be adjusted. Therefore, compared with N1, the achieved array gain in this network is reduced. However, this network is preferred in practice, since the number of phase shifters required in this network is significantly reduced to save energy consumption. This network imposes two hardware constraints: (i) the analog precoder/combiner should be a block diagonal matrix; (ii) all the nonzero elements of the analog precoder/combiner have the same fixed amplitude.

(N3) *Fully connected network with switches:* In this network, each RF chain is connected to all antennas similar to N1 but via low-

cost switches instead of phase shifters as shown in Fig. 2c. Each RF chain selects several antennas for communication, and the transmitted signals cannot be adjusted. Therefore, this network will suffer from serious degradation of array gain. However, as the phase shifters are replaced by simple switches, the hardware cost and energy consumption can be considerably reduced. In this network, all the elements of the analog precoder/combiner can be only selected from the set {0, 1}.

(N4) *Sub-connected network with switches:* In this network, each RF chain is connected to a sub-antenna array like N2 with phase

Millimeter-Wave (mmWave) Multiple-Input Multiple-Output (MIMO) Technique, Fig. 2 Analog circuit with different networks: (a) Fully connected network with phase shifters (N1); (b) Sub-connected network with

phase shifters (N2); (c) Fully connected network with switches; (d) Sub-connected network with switches; (e) Lens antenna array

shifters being replaced by switches, as shown in Fig. 2d. Each RF chain can only select a subset of antennas instead of the whole antenna array to transmit signals. Obviously, the achieved array gain is further reduced compared with N3. However, it also enjoys the lowest hardware cost and energy consumption, as it requires only a small number of switches without the need of splitters. The hardware constraints induced by this network are similar to those of N2, i.e., the analog precoder/combiner should be a block diagonal matrix, but its nonzero elements can be only selected from $\{0, 1\}$.

- (N5) *Lens antenna array*: An alternative quite different from the four networks discussed above is to utilize lens antenna array, as shown in Fig. 2e. The lens antenna array (a feed antenna array placed beneath the lens) (Brady et al. 2013) can realize the functions of signal emitting and phase shifting simultaneously. It can concentrate the signals from different propagation directions (beams) on different feed antennas. As the scattering at mmWave frequencies is not rich (Gao et al. 2018), the channel power will be concerted on only a small number of beams. Therefore, the simple selecting network with switches can be used to significantly reduce the MIMO dimension as well as the number of RF chains without obvious performance loss. Moreover, since all the phase shifters and splitters are replaced by one simple lens, the hardware cost and energy consumption of this network is also considerably low. Mathematically, the lens antenna array plays the role of a discrete Fourier transform (DFT). Therefore, in this network, each column of the analog precoder/combiner restricts to an DFT column.

Signal Processing for mmWave MIMO

The signal processing (including precoding/combining, channel estimation, and so on) for mmWave MIMO is also different from the

one for conventional MIMO since the fully digital architecture is replaced by the hybrid architecture.

We first discuss how to design the hybrid precoding (includes digital precoder and analog precoder) and combining (includes digital combiner and analog combiner) for mmWave MIMO with hybrid architecture. In general, the design target is to maximize the achievable sum rate. However, obtaining the optimal solution is not a trivial task, and the main difficulties are twofold. Firstly, the designs of digital precoder/combiner and analog precoder/combiner are coupled, which makes the optimization problem non-convex. Secondly, as described above, the analog circuit of hybrid architecture imposes non-convex hardware constraints on the analog precoder/combiner. To alleviate these two challenges, one feasible way is to decompose the original optimization problem into several subproblems, and each subproblem is approximated as a convex one and then solved by efficient convex optimization algorithms.

For example, in El Ayach et al. (2014), a spatially sparse precoding scheme is proposed for N1. It first assumes that the hybrid combiner at the receiver is ideal without any hardware constraint. Then, it approximates the sum-rate optimization problem as the one minimizing the distance between the optimal fully digital precoder without any constraint and the hybrid precoder. Then, a variant of the orthogonal matching pursuit (OMP) algorithm is developed to obtain the near-optimal hybrid precoder. Finally, the hybrid combiner can be designed in a similar way based on the effective channel. For N2, a successive interference cancelation (SIC)-based precoding scheme is proposed (Gao et al. 2016). Similar to the spatially sparse precoding scheme, it first decouples the design of precoder and combiner. Then, it decomposes the total achievable sum-rate optimization problem with non-convex constraints into a series of simple sub-rate optimization problems, each of which only considers one sub-antenna array. After that, it obtains the optimal hybrid precoding vector for each sub-antenna array, which is sufficiently close to the unconstrained optimal solution. Then, borrowing the concept of SIC for multiuser detec-

tion, the achievable sub-rate of each sub-antenna array is optimized one by one until the last sub-antenna array is considered. After that, the hybrid combiner can be obtained in a similar way based on the effective channel. Besides these two schemes, some other hybrid precoding and combining schemes designed for N1-N5 can be further found in Méndez-Rial et al. (2016).

The optimal performance of hybrid precoding and combining can be only achieved with perfect channel state information (CSI). However, for mmWave MIMO with hybrid architecture, estimating the complete CSI is not a trivial task (Alkhateeb et al. 2014). Firstly, due to the lack of antenna gain before the establishment of the transmission link, the SNR for channel estimation in mmWave MIMO is quite low. Secondly, the number of RF chains in hybrid architecture is usually much smaller than the number of antennas, so we cannot simultaneously obtain the sampled signals on all antennas. As a result, the traditional channel estimation schemes requiring the sampled signals on all antennas will involve unaffordable pilot overhead in mmWave MIMO. To solve this problem, two dominant categories of channel estimation schemes have been proposed.

The key idea of the first category is to reduce the dimension of channel estimation problem. For example, in Hogan and Sayeed (2016), a two-step channel estimation scheme is proposed for N5. In the first step, it performs the beam training between the transmitter and receiver to obtain the analog precoder and analog combiner. In the second step, the effective channel matrix in the analog domain is estimated by classical algorithms, such as least squares (LS). Note that the size of the effective channel matrix is much smaller than that of the original channel matrix. Therefore, the pilot overhead in the second step is quite low. The second category of channel estimation schemes is to exploit the sparsity of mmWave MIMO channels. Instead of estimating the effective channel matrix of small size, it can directly obtain the complete channel matrix with low pilot overhead. For example, in Alkhateeb et al. (2014), an adaptive channel estimation scheme is proposed for N1. It divides the total channel esti-

mation problem into several subproblems, each of which only considers one channel path. For each channel path, it first starts with a coarse angle of arrival (AoA)/angle of departure (AoD) grids and determines the AoA and AoD of this path belonging to which angle range by employing OMP algorithm. Then, the narrowed direction grids are used, and the direction of this path is further refined. Besides these two schemes, some other channel estimation schemes designed for N1-N5 can be further found in Méndez-Rial et al. (2016).

Key Applications

MmWave MIMO has been considered as a promising technique for further wireless communication systems. The applications of mmWave MIMO are immense. For example, mmWave MIMO could be used to enable high-rate low-latency data transmission for 5G cellular systems. In addition, with the recent excitement related to connected and autonomous vehicles, mmWave MIMO can play an important role in providing high data rate connections between cars. Finally, mmWave MIMO is also of interest for high-speed wearable networks that connect cell phone, smart watch, augmented reality glasses, and virtual reality headsets.

Future Directions

There are still some open issues on mmWave MIMO. For example, most of the existing signal processing for mmWave MIMO is designed under the narrowband and time-invariant channels. However, due to the large bandwidth and the high frequency, the mmWave MIMO channels are more likely to be broadband and time-varying, which incurs new challenges. Take the hybrid precoding for example. Broadband means that the analog precoder cannot be adaptively adjusted according to the frequency, leading to more difficulties in signal processing design, while time-varying means that we need to re-estimate the channel and re-compute the hybrid precoding frequently, leading to high pilot

overhead and computational complexity. Therefore, designing signal processing for mmWave under broadband time-varying channels will be an urging problem to solve.

Definitions

MIMO detection is to jointly detect multiple signals at the receiver, where the signals are transmitted through a wireless channel.

Historical Background

MIMO is an important technology in B3G/4G wireless communication systems, where both transmitters and receivers are equipped with antenna arrays. By exploiting the spatial diversity

benefitted from the multiple antennas, MIMO was first developed by Marconi in 1908 to combat channel fading. Then, the staff in Bell Laboratory extended this technology in different transmission environment. In 1995, Telatar studied the channel capacity of an $N_r \times N_t$ point-to-point MIMO system under Rayleigh fading condition and proofed that the achievable rate increases linearly with $\min(N_r, N_t)$ (Telatar 1999). This improved capacity is then regarded as the spatial multiplexing gain. In order to fully exploit the spatial multiplexing gain provided by MIMO systems, different Bell-Labs layered space time (BLAST) architectures were developed from 1996 to 1998 (Foschini 1996, 1999; Wolniansky 1998). As an opposite performance metric, spatial diversity gain is used to judge the transmission quality of a MIMO system. To maximize the diversity gain, Alamouti proposed a space-time block code (STBC) in 1998 (Alamouti 1998). With the STBC method, a full diversity gain, i.e., $N_t N_r$, can be obtained. In general, BLAST architectures using different MIMO detection schemes are always applied to achieve a high spectral efficiency without losing too much diversity gain. Thus, MIMO detection has been widely considered a key technology in designing MIMO systems.

Foundations

A typical MIMO system is shown in Fig. 1, where the transmission model is given by:

$$\mathbf{r} = \mathbf{H}\mathbf{s} + \mathbf{n}. \quad (1)$$

Here, $\mathbf{H}$, $\mathbf{s}$, and $\mathbf{n}$ denote the channel matrix, transmitted signal vector, and background noise, respectively. MIMO detection is to recover the

transmitted signal at the receiver, where the estimated signal is denoted by $\tilde{\mathbf{s}}$ in Fig. 1.

MIMO detection in uncoded systems In general, to obtain an optimal bit-error rate (BER) performance with a full diversity gain in uncoded MIMO systems, maximum likelihood (ML) detection method can be carried out by employing exhaustive search, where the estimated signal vector is derived as $\tilde{\mathbf{s}} = \arg \min_{\mathbf{s} \in \mathcal{S}^{N_t}} \|\mathbf{r} - \mathbf{H}\mathbf{s}\|^2$. Here, $\mathcal{S}$ denotes the symbol alphabet. Due to the involved constellation searching, the computational complexity of the ML method grows exponentially with the number of transmit antennas, which makes it infeasible to be applied in a real MIMO system. Then, several low-complexity detection schemes have been widely studied in literatures (Wolniansky 1998; Bai 2012; Yao 2002; Liu 2011). Among the proposed sub-optimal methods, linear detectors are extensively applied in practice, such as zero-forcing (ZF) and minimum mean square error (MMSE) linear filters (Bai 2012):

- *ZF detectors.* The signal received by a linear detector is filtered by a well-designed matrix which enables the transmitted multiple signal to be detected separately without involving interferences. For the ZF method, the filter matrix can be designed by inverting the channel matrix, i.e., $\mathbf{W}_{ZF} = (\mathbf{H}^H \mathbf{H})^{-1} \mathbf{H}^H$. Then, the estimated signal vector is given by:

$$\begin{aligned} \tilde{\mathbf{s}} &= \mathbf{W}_{ZF} \mathbf{r} \\ &= \mathbf{s} + (\mathbf{H}^H \mathbf{H})^{-1} \mathbf{H}^H \mathbf{n}. \end{aligned} \quad (2)$$

However, as the equivalent noise becomes $(\mathbf{H}^H \mathbf{H})^{-1} \mathbf{H}^H \mathbf{n}$ in (2), the noise power would be amplified if the channel matrix is not orthogonal. Furthermore, the ZF detector

MIMO Detection, Fig. 1

An illustration of a MIMO system

cannot offer a satisfied BER performance when the signal-to-noise ratio is low.

- **MMSE detectors.** In order to alleviate the co-channel interference while restraining the impact of background noise at the same time, the MMSE method was proposed. In an MMSE detector, the filter matrix is developed on the criterion of minimizing the estimation error, i.e., $\mathbf{W}_{MMSE} = \arg \min \mathbb{E}[\|\mathbf{s} - \mathbf{W}\mathbf{r}\|^2] = \mathbf{H}(\mathbf{H}^H\mathbf{H} + N_0/E_s\mathbf{I})^{-1}$. Here, N_0 and E_s denote the power of the noise and average signal, respectively. Compared with the ZF method, the filter matrix in MMSE approach can be designed by finding a balance between interference cancelation and noise amplification without incurring too much complexity.

Although the MMSE detector can improve the BER performance of ZF method, the noise will still be enhanced when filtering the co-channel interference. In Wolniansky (1998), a QR factorization-based successive interference cancelation (SIC) was proposed, where the detection of each signal can be carried out after removing the other estimated signals. Specifically, by multiplying $\mathbf{Q}^H$, where $\mathbf{Q}$ is the unitary component in the QR factorization of $\mathbf{H}$, the signal vector at the receiver is derived as

$$\begin{aligned}\mathbf{v} &= \mathbf{Q}^H\mathbf{r} \\ &= \mathbf{Q}^H\mathbf{Q}\mathbf{R}\mathbf{s} + \mathbf{Q}^H\mathbf{n} \\ &= \mathbf{R}\mathbf{s} + \mathbf{Q}^H\mathbf{n}.\end{aligned}\quad (3)$$

In (3), $\mathbf{R} = \mathbf{Q}^H\mathbf{H}$. Since $\mathbf{R}$ is upper triangular, signals in $\mathbf{s}$ can be estimated from the N_t th layer to the first layer in a successive manner. In summary, the SIC detector outperforms the above linear detectors because the noise would not be amplified by multiplying a unitary matrix.

In order to achieve the same diversity provided by the ML method, Yao (2002) proposed a lattice reduction-aided MIMO detection method. From the point of view of lattice decoding, MIMO detection is to find the closest vector point in a lattice generated by the basis vectors of the

channel matrix. Applying the Lenstra-Lenstra-Lovász algorithm (Lenstra 1982), a basis can be transformed into a nearly orthogonal one. Thus, the decoding radius is increased which helps to find the correct transmitted signal vector. Inspired by lattice decoding, Liu (2011) applied the Klein sampling algorithm Klein (2000) in MIMO detections. In this scheme, the searching area can be further extended by involving a randomized rounding instead of the conventional one.

MIMO detection in coded systems To improve both the channel capacity and BER performance, coded MIMO systems are widely considered, where the bit-interleaved coded modulation (BICM) is usually adopted at the transmitter (Caire 1998). At the receiver side, the iterative detection and decoding (IDD) architecture (Hochwald 2003) based on turbo principle is employed, which is shown in Fig. 2. With a soft-input soft-output (SISO) detector and a SISO decoder, the extrinsic information, i.e., log-likelihood ratio of each bit, is exchanged iteratively between them to obtain a good trade-off of the BER performance and complexity.

For MIMO detectors in IDD, the maximum a posteriori probability (MAP) method can provide an optimal BER performance. Unfortunately, since the MAP detector adopts the same exhaustive search with the ML method, the computational complexity becomes $O(2^{N_t}N_t^2)$ which also makes it infeasible to be implemented in a real MIMO system. In Wang (1999), an MMSE-based soft cancelation (SC) method was proposed to provide a sub-optimal performance with relatively low computational complexity. Since the MMSE-SC is developed on a symbol-wise linear filter, the offered BER performance is always taken as a benchmark when designing low-complexity sub-optimal methods. To improve the performance without incurring too much complexity, a bit-wise MMSE filter was studied in Li (2013). By exploring the distribution of the a posteriori probability of the transmitted signal vector, (Bai 2013) applied the Klein sampling in IDD and proposed an a priori information-based sampler. After that, Bai

MIMO Detection, Fig. 2 An illustration of a MIMO-BICM system

(2016) considered a large-scale antenna scenario and developed a Klein sampling-aided Markov chain Monte Carlo (MCMC) detector. In this scheme, the detection is carried out in a block-wise manner using the MCMC approach, while each block can be drawn with the Klein sampler.

Key Applications

MIMO detection is fundamental in wireless communication systems where the transmitter and the receiver are equipped with multiple antennas. Another typical application scenario can be found in multiuser detection.

Definitions

Multiple-input multiple-output (MIMO) relay refers to a cooperative communication technology employing relay nodes, when one or more nodes of a relay system have multiple transmit/receive dimensions. MIMO relay communications can improve the reliability and extend the coverage of communication systems.

Historical Background

A relay channel, also known as three-terminal communication channel, was first investigated in van der Meulen (1971). The capacity of this channel was studied in 1979 (Cover and El Gamal 1979). During 1980s and 1990s, further information theoretic results on the relay channel were discovered (Vanroose and van der Meulen 1992). Since the turn of the century, the relay channel has attracted a renewed interest due to the boom of applications of wireless communications (Sendonaris et al. 2003).

When multiple antennas are deployed at one or more nodes of the relay system, we call such relay system a MIMO relay channel. The achievable rate and capacity upper bound of a MIMO relay channel have been studied in Wang et al. (2005). A diversity-multiplexing trade-off of multi-antenna cooperative systems has been studied in Yuksel and Erkip (2007).

More applied issues of wireless relay system have been discussed in Sendonaris et al. (2003) in terms of user cooperation diversity, where the key idea is to enable multiple terminals (source and/or relays) to cooperate with each other to create a virtual antenna array that provides some form of spatial diversity. The authors of Sendonaris et al. (2003) showed that user cooperation is beneficial in terms of increasing system throughput and cell coverage, as well as decreasing sensitivity to channel variations.

Recent surveys on topics in *amplify-and-forward* (AF) MIMO relay systems can be found in Sanguinetti et al. (2012). A testbed implementation of MIMO relay system was reported in Maltsev et al. (2010). A general framework of optimizing the source and relay precoding matrices has been developed in Rong et al. (2009). There are special issues in *IEEE Journal on Selected Areas in Communications* on the topic of MIMO relay (Hua et al. 2012).

Foundations

The simplest MIMO relay system consists of three nodes as illustrated in Fig. 1, where one

MIMO Relay, Fig. 1

Block diagram of a dual-hop MIMO relay system

source node (S) transmits information to one destination node (D) with the aid of a relay node (R). Each node has multiple transmit/receive dimensions. Let us denote the number of dimensions at node i as N_i , $i \in \{s, r, d\}$. Mathematically the channel response from one node to another is represented through a matrix. As an example, the source-relay, relay-destination, and source-destination channels are represented by matrices $\mathbf{H}_{sr}$, $\mathbf{H}_{rd}$, and $\mathbf{H}_{sd}$, respectively. MIMO relay channel is an important extension of single-hop MIMO channel, which has been extensively studied in the last decade. Similar to a single-hop MIMO channel, the multiple transceiving dimensions (degrees of freedom) in a MIMO relay channel can be used to achieve various trade-offs between diversity gain and multiplexing gain (Yuksel and Erkip 2007), where the diversity gain helps improving the system reliability, while the multiplexing gain is mainly used to increase the system throughput.

Since each hop of the relay system in Fig. 1 forms a MIMO channel, the input-output relationship from node $j \in \{s, r\}$ to node $i \in \{r, d\}$ is given by

$$\mathbf{y}_i = \mathbf{H}_{ji}\mathbf{x}_j + \mathbf{v}_i \quad (1)$$

where $\mathbf{x}_j$ is the transmitted signal vector at node j with a dimension of N_j and $\mathbf{y}_i$ and $\mathbf{v}_i$ are $N_i \times 1$ vectors of received signal and noise at node i , respectively.

Compared with single-hop MIMO systems, dual-hop or multihop MIMO systems provide more freedoms to system designers. In particular, for an optimal dual-hop relay system performance, both of the transmitted signal vectors $\mathbf{x}_s$ and $\mathbf{x}_r$ from two different nodes need to be optimized, and both of the received signal vectors $\mathbf{y}_r$

and $\mathbf{y}_d$ at two different nodes need to be optimally processed. On the other hand, such a flexibility also makes the optimization problems much more challenging than those for single-hop MIMO systems. In fact, most of the optimization problems in MIMO relay systems are highly nonconvex involving multiple matrix/vector variables. As a matter of fact, except for some upper bounds (Wang et al. 2005), the exact capacity of a MIMO relay channel is still not available.

A relay can be half-duplex or full-duplex. A half-duplex relay receives and transmits in two separate time/frequency channels. A full-duplex relay receives and transmits at the same time and same frequency (Cirik et al. 2014).

Relay Strategies

An important part of a relay system is known as relay strategy, which determines how the relay processes $\mathbf{y}_r$ to generate $\mathbf{x}_r$. Mathematically, the relay strategy can be represented by a function of $\mathbf{x}_r = \mathbf{f}(\mathbf{y}_r)$, where $\mathbf{f}$ represents the relay strategy. Interestingly, so far, there is no relay strategy that works best under all scenarios. Generally speaking, there are two main categories of relay strategies: *regenerative* relay and *non-regenerative* relay. In a regenerative strategy, the relay node first extracts out (decodes) the information from $\mathbf{y}_r$. Then, the relay node generates $\mathbf{x}_r$ by re-encoding the information. This strategy is also known as *decode-and-forward* (DF). A relaxed form of this strategy is called *compress-and-forward* where the signal received at the relay node is partially compressed before it is

forwarded. There are also other variations of this strategy (Kramer et al. 2005).

For a *non-regenerative* strategy, the relay node only amplifies (including a possible linear transformation) and retransmits its received signals, without attempting to decode the information-carrying symbols. Thus, a non-regenerative relay is also referred to as AF relay. The authors of Fan and Thompson (2007) compared the performance-complexity trade-offs of non-regenerative and other MIMO relay techniques. Both regenerative and non-regenerative strategies are affected by the noise at the relay node, although in different ways. The complexity and the processing delay of a non-regenerative strategy are generally much smaller than those of a regenerative strategy. The non-regenerative strategy is also believed by many to provide a better trade-off between benefits and implementation costs.

With a linear AF relay, we can in general write $\mathbf{x}_r = \mathbf{F}_r \mathbf{y}_r$, where $\mathbf{F}_r$ is the relay amplifying (precoding) matrix.

Key Applications

Relay nodes are needed in situations where the path loss between source and destination is too high, and/or the transmission power from the source is too limited by regulation and/or hardware constraints. Relay nodes are easy to install to extend the reach of a backbone network. Special relay nodes can be equipped with multiple antennas to compensate the limitation of most user terminals such as handsets. Cooperative relay nodes can form a virtual multi-antenna relay (Sendonaris et al. 2003), which increases the spatial diversity order of the source-relay-destination channel and thus improves the reliability of communication.

MIMO relay has applications in many physical forms of communication channels, such as:

- Multi-antenna multihop wireless networks, which are perhaps the most commonly referred to in the context of MIMO relays.

Multihop wireless backhaul networks are being considered in several industry standards such as IEEE802.16j (Genc et al. 2008).

- Underwater acoustic relay channel. Since the bandwidth of underwater acoustic channel is inversely proportional to the transmission distance, MIMO relay techniques can enhance the capacity of underwater acoustic communication systems over a long distance (Al-Dharab et al. 2013).
- Wireline DSL relay channel, which can be modeled as MIMO relay channel due to the crosstalk arising from the electromagnetic coupling between neighboring twisted-pairs.
- Powerline relay channel. Recently, cooperative relay communication technology has been adopted into the indoor powerline communication environment (Wu and Rong 2015).

Definitions

Mining task offloading is a promising solution to address the computation-intensive mining tasks by offloading them to edge computing nodes using mobile edge computing technology.

Historical Background

Blockchain, the technology underpinning cryptocurrency, has been widely applied to many fields, such as security, smart cities, and supply chain UK Government (2016) and Iansiti and Lakhani (2017). However, the application of blockchain technology into wireless mobile networks is hindered by a main challenge brought by a computational process called

mining. Specifically, in order to confirm and secure the integrity and validity of transactions, the participants (a.k.a. miners) need to solve a computational difficult problem, i.e., the proof-of-work puzzle Beccuti (2017) and Kiayias et al. (2016), which sets an extremely high demand for the computational capabilities and storage availability of the miners.

To release the burden of the miners, *Mobile Edge Computing* (MEC) is considered as a promising solution that brings network resources closer to the end users, which can effectively reduce the energy consumption and shorten the transmission delay Stanciu (2013) and Xiong et al. (2017). As a key enabler of MEC, nearby resource-rich access points (APs) can process the users’ requests as a substitute of clouds, which is also called cloudlet and able to reduce the transmission delay due to its proximity to users Mao et al. (2017b), Wang et al. (2016), and Yu et al. (2016). Nonetheless, due to its limited computation capacity and storage space, it is difficult for each AP to handle a large amount of requests from the users at a time. Moreover, AP computation offloading may lose its advantages when the wireless channel is in deep fading or the user is far away from the AP. To avoid the global network bottlenecks, device-to-device (D2D) computation offloading acts as an additional type of edge computing is playing an increasing important role in enhancing MEC performance by exploiting surplus computing resources in neighboring user devices Mao et al. (2017a).

Therefore, there are mainly two offloading modes. One is “offloaded to the nearby AP” where the powerful computing capability enabled by the APs can be leveraged to enhance the task offloading performance. The other is “offloaded to a group of nearby users” (a.k.a. multiuser cooperative edge computing) where a group of users can share their computational resources to aid the computation process through D2D computation offloading. Accordingly, in MEC-enabled wireless blockchain networks, the mobile miners can resort to the nearby edge nodes (APs or mobile users) to perform the computation-intensive tasks.

Foundations

Since blockchain in general are currently employed in wired networks, a framework of wireless blockchain network with MEC is necessary to perform the mining task offloading. Figure 1 gives a brief framework of MEC-enabled wireless blockchain networks Liu et al. (2018), where both the APs and mobile users have a computation capacity to provide task-execution services. Accordingly, the computational difficult mining task can be offloaded in two ways: (1) The miners can offload the full mining task to a nearby AP. (2) The miners can divide the whole mining task into several parts and separately forward them to a group of nearby mobile users through D2D links.

Mining Task Offloading in Wireless Blockchain Networks, Fig. 1 An illustration of MEC-enabled wireless blockchain networks

Applying the blockchain technology to wireless networks induces several issues related to the resource allocation and management, which is an ever-popular topic in wireless networks. The most representative ones include:

- Offloading scheduling Liu et al. (2018): For the miners in wireless blockchain networks, offloading scheduling scheme including the offloading mode selection and offloading task allocation among two offloading modes is crucial to guarantee the miners' demands as well as balance the computation load of edge computing nodes.
- Resource pricing Xiong et al. (2017): In blockchain-based networks, the price setting of resources, an indispensable part in the incentive mechanism, plays an important role in coordinating the wireless resource allocation.
- Content caching: For the miners, some information related with the block (like the cryptographic hashes of blocks) and computation results need to be stored for future request. The caching strategy of miners (where to cache and which part to cache) coupled with the storage space allocation is a key factor for wireless blockchain networks.

Key Applications

Mining task offloading provides an effective way to address the computational intensive mining tasks for miners, which can facilitate the application of blockchain technology into wireless networks.

Mixed network, is a message routing protocol supporting sender and receiver anonymity by using a group of proxy servers, called mixes or stages. At each mix, a batch of inputs is mixing together and reordering to exit in a different order.

Introduction

Mixed network, or mixnet, is a message routing protocol supporting sender and receiver anonymity by using a group of proxy servers, called mixes or stages. At each mix, a batch of inputs is mixing together and reordering to exit in a different order. The first mixnet protocol was proposed by David Chaum in 1981 to achieve anonymity in electronic voting (e-voting) application. Consequently, many anonymity networks have been proposed, such as Crowds (Reiter and Rubin 1998), MixMaster (Cornelius et al. 2008), Freenet (Clarke et al. 2000), Tarzan (Freedman and Morris 2002), Tor (Dingeldine et al. 2004), GUNet (<https://gnunet.org/>), and I2P (<https://geti2p.net/>). Additionally, the mixnet also provides message integrity and verifiability. From performance perspective, the mixnet should acquire less network latency and high throughput. The goal of mixnet is either to support one (sender) or two-way (sender and receiver) anonymity.

In the context of wireless networks, many types of applications use mixnet routing, including e-voting, anonymous e-mails, and location privacy in wireless networks (Lu et al. 2009). For secure and error-free election, the e-voting system requires verification of voter eligibility, ballot integrity, and tally accuracy. For anonymous e-mails, mixnet should apply reliability to anonymous Internet communications to assure detecting any misuse of anonymous emails senders. Also, location privacy applications can be efficiently used with anonymous sender, such as Radio frequency identification (RFID) tags anonymity (Lin et al. 2010).

Applications employing mixnet routing protocol face passive and active attacks (Duddu and Samanta 2018). Passive attacks, also called traffic analysis, have the goal of correlating inputs to corresponding outputs at each mix stage, while active attacks, also called traffic manipulation, have the goal of controlling one or more mix stages to attack message integrity.

Mixnet Types

The topology of the mixnet can be cascade or free-route (Taha and Shen 2013), as illustrated in Figs. 1 and 2, respectively. On one hand, the mixes in the cascade mixnet are ordered in sequential and every batch of inputs should go through all mixes in the network. On the other hand, the free-route mixnet is not restricted to a fixed group of mixes and all inputs may traverse different paths in the network. Depending on mixing operation types, the mixnet implements one (or the two) of those topology types. Additionally, those mixing operations are categorized into decryption, hybrid, re-encryption,

Mixed Network, Fig. 1 Cascade mixnet topology

Mixed Network, Fig. 2

Free route mixnet topology

and universal re-encryption mixnet (Sampigethaya and Poovendran 2006).

In decryption mixnet, the sender uses each mix's public key to repeatedly encrypt the message, starting with the first mix to the receiver and ending with the first mix to the sender. In each encryption, the sender adds the next mix's address; hence, each mix knows the next mix's address only when decrypting the message. Only the last mix knows the receiver, x , of the message when decrypting the message. Equation (1) shows the encrypted message transferred from the sender, s .

$$E_K(m, r) = A_1 \| E_{K_1} (A_2 \| E_{K_2} (A_3 \| \dots \| E_{K_{n-1}} (A_n \| E_{K_n} (A_x \| E_{K_x} (m) \| r_n) \| r_{n-1}) \dots \| r_2) \| r_1) \quad (1)$$

where $E_K(m, r)$ is an encryption operation, El Gamal or RSA encryption, using a public key K , A_i is the address of a mix i , and r_i is a random number generated by a mix i . This type of mixing is not only used for sender anonymity,

but it also can be used for two-way anonymous communications to achieve receiver anonymity. This can be achieved by adding to the previous equation the Return Path Information (RPI), which includes the return information encrypted using sender's public key, K_s . However, using many public key operations may limit the mixnet high-latency applications.

For hybrid mixing, the public key is used only to encrypt the shared keys, sk , between the sender and every mix in the network. The shared keys are used in encrypting the transmitted messages as illustrated in Eq. (2)

$$E_K(m, r, sk) = A_1 \| E_{K_1} (sk_1) \| E_{sk_1} [A_2 \| E_{K_2} (sk_2) \dots \| E_{sk_n} [A_n \| E_{K_n} (A_x \| E_{K_x} (m) \| r)] \dots] \quad (2)$$

For re-encryption mixnet type, the encrypted message does not have to go through all mixes, i.e., free-route mixnet is more suitable for this type. Additionally, and unlike other mixnet operation types, the length of the message does not

changed as the message goes through mixes. The reason of this fixed length message is that the sender uses an encryption key, which is a combination of all mixes' keys. In other words, Eq. (3) shows the encryption message produced at the sender

$$E_K(m, r) = (g^r \| (A_x \| m) K^r) \quad (3)$$

where g is the generator of a finite group Z_p , and K is the public key of the mixnet, calculated as follows:

$$K = \prod_{j=1}^n K_j = \prod_{j=1}^n g^{d_j} = g^{\sum_{j=1}^n d_j} \quad (4)$$

However, to achieve multicasting transmission, (i.e., transmitting to multiple receivers), all mixes in the re-encryption mixnet must share their key and perform decryption after mixing to get the address of the receiver. Such dependency can be avoided when using the universal re-encryption mixnet, where the sender transmits two encrypted messages: one for the original message and the other for the receiver's public key used to encrypt this original message, as illustrated in Eq. (5).

$$E_K(m, r) \| E_K(1, r') = (g^r \| m K^r) \| (g^{r'} \| K^{r'}) \quad (5)$$

Table 1 shows a comparison between the different mixing types of mixnet

Degree of Anonymity

The degree of anonymity, d , is a measure of anonymity level achieved when applying the mixnet protocol, and this level varies depending on the supported applications. For instance, in e-voting, the voter's identity should be totally hidden, while in electronic payment system, seller's identity can be revealed by an authorized party in order to solve any dispute.

According to Reiter and Rubin (1998), the degree of anonymity is defined as: $d = 1 - p$,

where p is an attacker probability about a potential sender. Additionally, Entropy is employed as a measure of the degree of anonymity as follows (Diaz 2006):

$$H(x) = \sum_{i=1}^N \left[p_i \log \frac{1}{p_i} \right],$$

where N is number of nodes inside the network and p_i is the probability associated with a node i . For a uniform distribution, all nodes have an equally likely probability of $\frac{1}{N}$ and Entropy records a maximum, H_M . Therefore, the degree of anonymity can be calculated as follows: $= \frac{H(x)}{H_M}$.

The effective anonymity set size, N , is another factor in measuring the degree of anonymity, which increases as the set size increases.

Mixnet-Based Wireless Applications

Shuffling protocol (Peng 2011) is employed to implement the mixnet, in which re-encryption followed by shuffling proof operations is applied on the group of ciphertext. Shuffling proof is a complex process, used to prove that the permutation of the input results the correct output. Shuffling protocol should support correctness, soundness, and zero knowledge privacy. Correctness means that shuffling inputs specific batches to get intended output, soundness means to verify the correctness of shuffling, and zero knowledge privacy means that it is impossible to reveal the permutation used in shuffling operation.

Another mixnet-based project is the Participatory sensing system (PSS) (Peng 2011), which is a data collection, processing, and dissemination system that is cost-effective and reliable. The system monitors a set of assets, called point of interest (POIs), by a group of entities, such as mobile nodes, which are participating to observe the assets and send their observed information to the application server. Based on the idea of mixnet, if the observer senses the attribute of POI, it sends an anonymous observation report to the application server. In order to anonymously send the report, the observer entity transmits the report

Mixed Network, Table 1 Mixnet types comparison

	Decryption	Hybrid	Re-encryption	Universal re-encryption
Mix type	Cascade	Cascade	Cascade and free route	Free route
Multiple receiver	Not applied	Not applied	Could be applied	Could be applied
Anonymity	One-way, could be two-way by adding RPI	One-way, could be two-way by adding RPI	Two-way is possible	One-way only
Message Integrity	Using public-key encryption	Using public and symmetric keys	Using El Gamal encryption	Using El Gamal encryption
Verifiability (Puiggali 2010; Chen 2007)	Using public key verification techniques	Using public key verification techniques	Using El Gamal verifications	Using El Gamal verifications
Fault Tolerance	Not applied	Not applied	applied	applied
Latency	High	Higher	Medium	Low
Throughput	lower	Low	Medium	High
Scalability	Not applied	Not applied	Could be enhanced	Could be enhanced
Efficiency	Low	Low	Medium	Medium

to another entity in the network and identifies specific number of hops for the message to circulate before receiving to the application server.

The Onion Routing (Tor) (Burke et al. 2006) is another predecessor for mixnet to achieve anonymous communications, in which the message has layers of encryption, and one layer is peeled at a time as the message traverses through Tor volunteering servers. However, Tor faces obfuscations of limited capacity and performance due to relaying on volunteering servers. In (The Tor project 2003), a Software-Defined Networking (SDN)-based Onion Routing (SOR) is proposed as a novel Cyber anonymity using Tor (Elgzil et al. 2017). The goal is to leverage the large capacities, strong connectivity, and economies of scale inherent to commercial data centers, by building onion routing tunnels over anonymity service providers.

mobile cellular network; Mobile content delivery architecture

Definition

Mobile content distribution architecture is a promising technique to optimize the mobile content delivery and decrease duplicate transmission by offering flexible storage capability in mobile network, which can utilize network resources in a more efficient manner and improve end users' Quality of Experience (QoE).

Foundations

In recent years, to reduce mobile core network traffic and deliver content efficiently over the cellular network, many content distribution architectures have been proposed. Mobile content delivery network (CDN), mobile edge computing (MEC), and information-centric networking (ICN) are the representative architectures. So in this section, we briefly present the research on the three emerging content distribution techniques.

Mobile CDN

In the past decade, CDN has become the most popular and widely used content distribution architecture in the current wired Internet. Today, a large fraction of Internet traffic is delivered by CDN. Although CDN works very well in wired networks, it cannot be deployed in mobile networks directly. CDN is not suitable for mobile networks for two reasons. Firstly, CDN systems just help clients to select the "best" server at the initial stage and do not consider clients' mobility. Secondly, DNS-based schemes are used in traditional CDN systems to select cache servers and perform load balancing. Nevertheless, in a highly volatile mobile environment, user equipment (UE)'s location and IP address can change over time rapidly, which makes the address not always truly reflect the position of a UE. Thus, how to deploy CDN in mobile network becomes an interesting research direction.

One feasible mobile CDN implementation solution to address the scalability and mobility issues of the mobile networks is jointing distributed mobility management (DMM) and CDN (Liebsch and Yousaf 2013; Munaretto et al. 2014). DMM has been proposed by the Internet Engineering Task Force (IETF) as a new paradigm for flat networks in 5G mobile architectures to enable IP address continuity in DMM. Other mobile CDN implementation solutions have also been studied. Literatures (Dramitinos et al. 2013; Pentikousis et al. 2013) utilize the emerging software defined networking (SDN) approach to increase the operators' innovation potential and support video services more effectively.

MEC

With the evolution of mobile base stations and the emergence of cloud computing technology, edge computing as a novel paradigm has attracted widespread attention. In recent years, a few edge computing architectures have been presented, such as Cloudlet, Edge Computing, Fog Computing, Mobile Cloud Computing (MCC), Mist Computing, and MEC (Mach and Becvar 2017). Among all these edge computing architectures, MEC is the most popular architecture. MEC has been proposed by the standards institute ETSI (European Telecommunications Standards Institute) as a promising technology to reduce the load of mobile core network by shifting computational capability from the core network to the mobile edge (i.e., the radio access network). The key characteristics of MEC are proximity, lower latency, and location awareness. The MEC white paper has been issued in 2014 (Patel et al. 2014). MEC is an emerging technology, which is very likely to be applied in 5G mobile networks. Thus, there is a trend of integrating content distribution with MEC to improve content delivery efficiency and reduce content delivery delay.

ICN

Over the past several years, the research on the content distribution architecture is from two approaches: "clean slate" and "evolutionary".

Mobile CDN and MEC all belong to the “evolutionary” approaches. However, ICN (Xylomenos et al. 2014; Xie et al. 2017c) is the representative of “clean slate” approaches. The key concept of ICN is the content-centric communication model instead of the end-to-end communication model in traditional networks. So far a few ICN architectures have been proposed, such as Data-Oriented Network Architecture (DONA), Publish Subscribe Internet Technology (PURSUIT), Architecture and Design for the Future Internet (4WARD), Scalable and Adaptive Internet Solutions (SAIL), and Named-Data Networking (NDN). Although the concept of ICN has already attracted great attention in academia and industry, the deployment of ICN needs to update all network elements, user devices, as well as origin servers to be ICN-aware. In this case, the pure commercial ICN deployment would not be done in the near future. So literatures (Veltri et al. 2012; Vahlenkamp et al. 2013; Chanda and Westphal 2013; Chang et al. 2014) have studied the issue on how to deploy the ICN architectures in the legacy IP network.

Future Directions

Despite the potential vision of these mobile content distribution architectures, many significant research challenges remain to be addressed by future research efforts. In this section, we discuss some of these challenges and present some future research directions.

Adaptive Video Content Distribution over Cellular Networks

In mobile cellular networks, due to the varying wireless network conditions and the diversity of end-user devices, different users should be served with different data rates to enhance the users’ QoE. Researchers have proposed various techniques to provide better QoE for mobile users by adapting multimedia content over wireless channels real-timely. Recently, the Scalable Video Coding (SVC) (Xie et al. 2017b) and HTTP Adaptive Bit Rate (ABR) streaming (Xie et al. 2017a) have been considered as the main

solutions. In SVC, each video is encoded into one mandatory base layer and several optional enhancement layers. The enhancement layers build upon the base layer and provide multiple qualities. In HTTP ABR streaming, a video is divided into a series of small video chunks with a typical time duration of 2–10 s, and each video chunk is encoded into multiple bitrates (i.e., qualities). A client can adaptively request a video content with different qualities according to its wireless network condition. Caching adaptive video content in Radio Access Network (RAN) is a promising way to provide better content delivery service and to improve content distribution efficiency (Xie et al. 2016). In this scenario, how to allocate limited cache resource for adaptive video contents has become an important issue. Therefore, it is necessary to design effective cache resource allocation schemes to optimize the adaptive video content placement.

HTTPS Traffic Processing Strategies

Most of the current works on content distribution solutions are studied especially for HTTP traffic. With increased emphasis on privacy, security, and regulatory compliance, organizations and companies are more and more dependent on encryption technologies to protect information, among which TLS/SSL have become the standard of choice for providing secure applications. For instance, TLS/SSL are used by HTTPS to ensure secured transactions. On the other hand, with the rapid development of processing technologies, the cost to encrypt data is falling rapidly. Unfortunately, once an encrypted connection between a client and a server is established, it is difficult to manage, accelerate, or audit activity due to the private nature of the TLS/SSL tunnel. Therefore, it is necessary to study how to solve the HTTPS traffic processing problem in content distribution framework in the future.

Combining with Network Function Virtualization and Cloud Computing

With the rapid development of processing and virtualization technologies, computing resources

have become cheaper, more powerful, and more ubiquitously available than ever before. Network Function Virtualization (NFV) is a promising technology which decouples network functions from the underlying specialized hardware to make the network architecture more flexible and open. The NFV and cloud computing technologies draw ISPs' attention because they can reduce operators' capital expenditures for scaling up the network and make network reconfiguration quick and adaptive. Therefore, the deployment of content distribution architecture combining with NFV and cloud computing technologies is another future research direction.

Key Applications

Mobile content distribution architectures can be deployed in mobile networks to provide better content delivery service and improve end users' QoE.

Mobile Crowdsensing: Issues and Challenges

Yang Liu

State Key Laboratory of Networking and Switching Technology, Beijing University of Posts and Telecommunications, Beijing, China

Synonyms

Crowdsensing; Crowd sensing

Definitions

Mobile crowdsensing can be referred to as crowd sensing or crowdsensing, which is from the idea of crowdsourcing. Crowdsourcing comes from “wired” magazine which describes a novel distributed problem-solving and working model in which companies allocate tasks through the Internet, find ideas, or solve technological problems (Ganti et al. 2011). Recently, the idea of crowdsourcing has been combined with mobile sensing and uses the mobile devices as basic sensing units. The network forms a crowdsensing network, which realizes the distribution of sensing tasks and the collection of data.

Historical Background

At present, the Internet of Things has developed deeply, and the need for physical environment sensing is very thorough. With the development of wireless communication, smartphones, tablets, wearable devices, and mobile terminals such as in-vehicle sensing devices integrate more and more sensors. With the increase number of wireless mobile devices, more than a dozen people have been developing how to use specific consciously deployed sensors to provide sensing services. Also, the Internet of Things will provide more large-scale, complex, and comprehensive sensing services, thus entering a new era of development.

Foundations

In traditional networks, people usually consume sensing data. In crowdsensing, however, people serve both as a “consumer” of sensing data and as a “producer” of sensing data, using a popular new word, which is called “prosumer.” This basic human-centered feature brings unprecedented opportunities for IoT sensing and transmission. The specific performance is as follows:

- The costs of network deployment are lower. First, mobile devices do not require special deployment. Second, people help data sensing and transmission. As users who carry the devices arrive at different places, they can sense anytime and anywhere; on the other hand, due to the contacts between mobile users, they can use “storage-carry-forward” opportunistic transmission mode in an intermittently connected environment (Liu et al. 2018).
- Network maintenance is simpler. First, the users usually have better energy supply, computing, storage, and communication capabilities. Second, the mobile devices are usually kept by their holders, so they are usually in a better working state. For example, people can always charge mobile devices when their mobile phones are needed.
- The crowdsensing system is large scale. We need to recruit more users to participate in the system when there are more tasks.

Due to the above advantages, the crowdsensing network has become a new and important way to sense for the Internet of Things.

A typical crowdsensing is usually composed of a sensing platform and multiple users. Multiple servers are in the platform; the users can utilize various sensors embedded in the smart phones, e.g., GPS, accelerometer, gravity sensor, gyroscope, electronic compass, light distance sensor, microphone, cameras, etc., to collect various data and move through cellular networks and report the data. The workflow is as follows:

- **Task publishing:** data demanders publish tasks on the platform. There are two methods to assign tasks: pull-based method and push-based method. Pull-based method refers to that participants browse and retrieve tasks from the platform and actively register as workers of a task; push-based method refers to that the platform finds suitable candidates from all participants. No matter which task assignment method is adopted, when the participants accept the task, they will become a worker of the task;
- **Task execution:** one worker arrives at the designated place according to the task requirements and uses a specific application which automatically saves sensor data according to the task requirements. For real-time sensing tasks, workers must upload data immediately; for nonreal-time sensing tasks, workers are allowed to choose the most economical communication mode to upload data before the task deadline;
- **Data aggregation:** affected by the distributed sensing mode, there are a lot of redundant, i.e., low quality or repetitive data. In the data aggregation stage, the platform filters and optimizes the data according to the task requirements and selects the high-quality data set that meets the task requirements;
- **Result handover:** data demanders can download data aggregation results from the platform before or after the end of the task. Most mobile crowdsensing tasks are difficult to define data collection constraints accurately at the very beginning. Therefore, the platform allows data demanders to see data aggregation results before the end of the task, so that the data demander has the opportunity to adjust the task requirements before the end of the task.

Key Applications

Mobile crowdsensing can be applied in many important fields, such as intelligent transportation, public transportation, tourism encyclopedia, indoor positioning, information dissemina-

tion, news reporting, and event sensing. Some typical applications are listed below:

- **Intelligent transportation.** Gazetiki (Popescu et al. 2008) is an application that uses Wikipedia and web search to build a geographic encyclopedia. Gazetiki first identifies all geographical names and their coordinates through Wikipedia and classifies and sorts them. When users search geographic information, Gazetiki shows them detailed geographic information and relevant photos. ParkNet (Mathur et al. 2009) uses GPS and the ultrasonic sensor installed on the right door to detect the empty parking space and share the detection results; the literature in (Zhou et al. 2012) designs the bus arrival time prediction system under Android platform.
- **Shopping.** Mobishop (Sehgal et al. 2008) collects people's shop ticket photos, extracts commodity prices through OCR character recognition technology, and pushes the collected commodity price information to different customers, so that people can share commodity price information.
- **Entomology.** Lostadybug (Losey et al. 2012) is a project to collect Ladybug photos, which is used to study Ladybug species, living conditions, and habits. As of March 2017, the website has collected 38,000 data from all over the world.
- **Environmental monitoring.** Creekwatch (Kim et al. 2011) is developed by IBM to monitor river water quality. When people pass a stream or river, the creekwatch application will submit the status of the river in its current location, the status includes the amount of water and waste, and it will also submit some photos. Creekwatch shows people the status of rivers around the world through a website.
- **Emergency aid.** Wreckwatch (White et al. 2011) can detect the accident through the sensor of mobile phone in the car and then find passersby to take photos of the scene of the accident and send them to the rescue center, so that the rescue workers can judge the location of the accident and the emergency degree of the rescue timely and accurately.

- News reporting. When there is a special event, Mediascope (Jiang et al. 2013) will retrieve all kinds of photos from the mobile photo album shared by the witnesses on the scene for the purpose of news reporting. The retrieval conditions include image similarity and geographic information.
- Information dissemination. Fliermeet (Guo et al. 2014) collects photos of public posters in the city; calculates the relationship among people, posters, and places; constructs the preferences of different individuals for different types of posters; pushes the posters they like or need to different people; and improves the communication efficiency of urban information.
- Enjoying flowers. SakuraSensor (Morishita et al. 2015) judges the sakura blossom situation through the video clips people take in the car during the sakura blossom season and calculates the optimal route to visit the cherry blossom beauty according to people's driving path.
- Indoor locating and navigating. An image-aided positioning system called Argus (Xu et al. 2015) is based on mobile terminals. Argus extracts geometric constraints from the image data of crowdsourcing and maps these geometric constraints to RSS fingerprint space to distinguish the location information of similar fingerprints and reduce the fuzziness of fingerprints.

Problems and Challenges Faced by Crowdsensing

Crowdsensing provides a new way to realize in-depth sensing but also brings new challenges to the research of theory, technology, and application. It can be summarized as the following aspects:

- The efficient transmission of crowdsensing data. Many crowdsensing applications need to continuously collect sensory data and transmit it to the data center. Reporting the sensing data

based on the connection between the mobile cellular network and the Internet will consume too much user equipment power and data traffic, resulting in greater pressure for the mobile cellular network. Therefore, it is necessary to design energy-efficient data transmission methods, such as based on short-range wireless communication.

- Resource optimization of crowdsensing networks. Overcoming the resource constraints of mobile nodes in terms of energy, bandwidth, computing, etc. is the key to the practical application of crowdsensing networks. First, because the number of users and the availability of sensors can change dynamically over time, it is difficult to accurately model and predict energy and bandwidth requirements to complete a specified task. Second, it is necessary to consider how to select a valid subset of users and reasonably schedule the sensing and communication resources under resource constraints.
- Incentive mechanisms of crowdsensing networks. A crowdsensing application relies on a large number of ordinary users to participate, and users will consume their own equipment power, computing, storage, communication, and other resources and bear the threat of privacy leakage when participating in sensing. Therefore, a reasonable incentive mechanism is needed to pay for user participation. The cost is compensated to attract enough users to ensure the quality of the data collection required.
- User privacy protection. By collecting the sensing data which is related to a user's position, the accurate position information of the user can be obtained (Liu et al. 2019b). Through long-term monitoring and analysis of location information, the user's home and work addresses, daily activity scope, and common traffic routes can be found. Mining the sensing data of motion state sensor can obtain the sensitive information of a user's daily life habit, health status, and so on; combining with the environment sensing data, it can also get the user's situation at any time. Although the large-scale collection

of sensitive sensing data of mobile intelligent terminals can analyze and mine many valuable information, such as urban traffic congestion, road conditions, air quality, environmental pollution, infrastructure conditions, public services, etc., once these sensing data is leaked, it will seriously threaten the privacy of users, so it is necessary to take effective measures to protect users' privacy.

- Data and platform security. Since the mobile crowdsensing network gathers a large number of sensitive and private data and can mine a large number of information with great application value, it will greatly increase the risk of hacker attack and confidential data disclosure (Liu et al. 2019a). How to better protect the security of data and platform has become a prominent and urgent key issue.
- Data authenticity and integrity. To build an efficient and valuable mobile crowdsensing network depends on users to provide authentic, complete, and reliable sensing data. However, for collecting sensing data, malicious users may submit false sensing data; or, for sensing data transmission, they may lose some data, which may lead to mining out wrong information and making wrong decisions. Therefore, it is very important to take corresponding technical measures to ensure the authenticity and integrity of data.
- The balance between the improvement of sensing quality and efficiency and the optimal utilization of resources. Due to the large number of sensors and the dynamic change of performance, the task allocation and resource consumption prediction under resource constraints become more complex and difficult (Liu et al. 2017). We can collect the sensing data of different types of sensing devices to achieve the same sensing goal, but the sensing quality and resource consumption are different. For example, location information can be mined by collecting sensing data from GPS, Wi-Fi, and mobile cellular networks. GPS has the highest location accuracy and resource consumption. Therefore, the balance between sensing quality and resource consumption

needs to be solved. In addition, it is possible to execute multiple priorities and different resource consumption sensing tasks on the same sensing device at the same time.

Technical Background

The past decades have witnessed the proliferation of smart wireless devices and mobile Internet services, yielding a rapid growth of the data-hungry mobile applications such as video surveillance, online gaming, and augmented/virtual reality. These applications have resulted in a tremendous traffic pressure in radio access networks (RANs) of wireless networks due to the limited radio resources. Conventional wireless infrastructures in RANs require to deliver the mobile users' data directly through the infrastructures, e.g.,

marco/micro base stations (BSs) and Wi-Fi access points (APs), which thus lead to a tremendous traffic pressure in RANs. For instance, due to the limited radio resources, mobile users might suffer from traffic congestion when delivering traffic through a same BS/AP at a hot spot and during the peak hours. Moreover, the interference/congestion may also lead to excessive energy consumptions of mobile users. Device-to-device (D2D) communication, an emerging paradigm in the fifth generation (5G) cellular networks, provides a promising efficient approach to accommodate the traffic demands. Instead of requiring the traffic to traverse through the cellular BS, D2D communications allow two nearby mobile stations (MSs) to perform a direct communication by using either the licensed inband spectrums or the out-band spectrums. Exploiting the close proximity between the MSs, D2D communications can bring lots of benefits, e.g., enhancing throughput, reducing traffic delay, and saving energy consumption. In particular, exploiting D2D communications to actively offload users' traffic has been envisioned as an efficient approach to relieve the traffic pressure in RANs and improve the efficiency in radio resource utilization (Li et al. 2014; Han et al. 2010; Wu et al. 2017, 2018a; Chuang and Lin 2012; Al-Kanj et al. 2014; Gao et al. 2014).

A concrete example of the D2D-assisted data offloading for content distribution in wireless network is shown in Fig. 1. Specifically, there exist a group of MSs, denoted by $\mathcal{U} = \{1, 2, \dots, U\}$, coexisting in a given area, and there exist a group of content blocks (CBs), denoted by $\mathcal{K} = \{1, 2, \dots, K\}$, available at the BS. We use L^k to denote the size of CB k . Each MS i is interested in receiving a subset of $\mathcal{K}$, and we use a U -by- K matrix $\mathbf{A}$ to denote the relationship between the MSs and the CBs, i.e., $A_{i,k} = 1$ if MS i is interested in obtaining CB k , and $A_{i,k} = 0$ otherwise. Set $\mathcal{C}_i$ denotes the set of the interested CBs which MS i wants to receive, i.e., $\mathcal{C}_i = \{k \in \mathcal{K} | A_{i,k} = 1, i \in \mathcal{U}\}$, and set Ω^k denotes the set of MSs which are interested in obtaining CB k , i.e., $\Omega^k = \{i \in \mathcal{U} | A_{i,k} = 1, k \in \mathcal{K}\}$. The group of MSs are in close proximity. To deliver CB k to all MSs in Ω^k , the D2D-assisted offloading mecha-

nism works as follows: The BS determines the transmission rate r^k of CB k , which is equivalent to its transmission duration $x^k = \frac{L^k}{r^k}$. The BS first sends part of data of CB k to some selected MS i , and meanwhile, MS i relays its received data via broadcasting to the other MSs in Ω^k . Let z_i^k denote the relaying duration of MS $i \in \Omega^k$ for CB k . There exists $\sum_{i \in \Omega^k} z_i^k \leq x^k$, the network scenario with $\mathcal{U} = \{1, 2, \dots, 8\}$, $\mathcal{K} = \{1, 2, 3\}$, and the detailed matrix **A**. Figure 1b, c, and d illustrate the process of distributing CB 1 to MSs 1, 4, 6, and 7 in a step-by-step manner, i.e., including Phase-I, Phase-II, and Phase-III, respectively. Figure 1b and c illustrate Phase-I and Phase-II of relaying through MS 1 and MS 4, respectively. In Phase-I, MS 1 sends its received data to MSs 4, 6, and 7. In Phase-II, MS 4 sends its received data to MSs 1, 6, and 7. Finally, taking into account the MSs' limited transmit powers and energy capacities, in Phase-III, the BS directly broadcasts the rest data of CB 1 to the MSs in Ω^1 for finishing the delivery of CB 1. Let z_B^1 denote the duration for the BS to perform this broadcasting. Then, there exists $z_B^1 + \sum_{i \in \Omega^1} z_i^1 \leq x^1$. Figure 1d shows the case of BS's broadcasting to all MSs in Phase-III.

The D2D-assisted data offloading has attracted lots of interests, which can be in general categorized into two groups. The first group of studies focused on exploiting the D2D-assisted offloading for delay-tolerance applications. For instance, in (Li et al. 2014), a delay-tolerant network (DTN)-based offloading problem has been studied, which jointly takes into account the heterogeneous data traffics, users' different interests, and the limited storage resources. In (Han et al. 2010), accounting for the feature of mobile social networks, a target set selection problem for D2D-assisted information distribution has been investigated. In (Chuang and Lin 2012), exploiting the features of the encounter frequency and social communities, a community-based opportunistic D2D information dissemination scheme has been proposed, with the objectives of minimizing cellular traffic load and delivery time. The second group of studies focused on

exploiting the D2D-assisted offloading for delay-sensitive (real-time) applications. For instance, in (Al-Kanj et al. 2014), the authors investigated how to separate the mobile users into different groups and to select a leader of each group for distributing the contents.

Key Applications

The above mobile data offloading via D2D-assisted communications can be used for lots of applications. The following are two typical examples.

- *Vehicular networks*: The emerging vehicular communications/networks require data and message transmissions between the moving vehicles and infrastructures (e.g., roadside units (RSUs)) as well as the transmissions between the moving vehicles. Taking into account the mobility of vehicles and the delay requirement of data transmissions (e.g., for the safety-oriented applications), exploiting the D2D-assisted data offloading among the vehicular users provides an effective approach to improve the throughput and reliability of vehicular data transmissions.
- *Mobile edge computing*: Mobile edge computing (MEC), which enables mobile terminals to offload the computation tasks to nearby edge servers/terminals with sufficient computation resources, has been considered as a promising approach to implement the emerging computation-intensive mobile internet applications (e.g., augmented/virtual reality). However, MEC involves intensive data transmissions between the mobile terminals and the edge servers (e.g., a mobile user offloads its computation task to an edge server), which thus necessitate resource-efficient data transmissions with low latency and high throughput. The D2D-assisted data offloading has been envisioned as a promising approach to achieve this objective, and the recent advanced non-orthogonal multiple

Mobile Data Offloading via D2D-Assisted Communications in Wireless Networks, Fig. 1 An example of the D2D-assisted data offloading for content distribution

access (NOMA) (Wu et al. 2018b) also facilitates the massive D2D communications for data offloading.

HetNet; Mobile edge caching

Definition

Mobile edge caching refers to distributing content files (e.g., videos, audios, photos, application programs, and so on) from service providers over the Internet to caches that are deployed at the edges (e.g., mobile devices and base stations) of mobile networks, aiming at bringing content closer to mobile users in the distance of the network topology to deal with the challenge of the explosive growth in content requests from users in mobile networks. HetNet is short for heterogeneous network and is a form of radio access networks (RANs) with complex interoperation between macro cells and small cells, which consists of different types of base stations (BSs) such as femto BSs, pico BSs, micro BSs, and macro BSs.

Mobile edge caching in HetNets is the combination between the technique of mobile edge caching and the network architecture of HetNets, aiming to achieve their joint benefits in enhancing network performances. Due to the high disparity of content popularity (i.e., a small number of content files actually may attract a large amount of downloads), by deploying hierarchical collaborative caching at the edges of HetNets, the content delivery cascades can be optimized during the intermediate transmissions, while reduced content delivery delays can be also provided.

Historical Background

With the rapid advancement of mobile networks from 2G and 3G to current 4G, people's daily life has changed significantly, and people are increasingly enjoying online social activities on mobile devices (e.g., smartphones and electronic tablets). As a result, requests for various content files (e.g., videos, audios, photos, application programs, and so on) from mobile users are increasing at an explosive speed, which has become a serious issue of mobile network operators (MNOs). However, current RANs and backhaul networks cannot support these content requests effectively due to the scarcity of network resources and the limit of their network architectures (Wang et al. 2015). Thus, to deal with those issues, it is necessary to employ revolutionary schemes in network architectures and data transmissions toward the fifth-generation (i.e., 5G) mobile networks.

Mobile edge caching is regarded as an effective technique to reduce the reduplicated network traffic load in mobile networks. In particular, studies in (Cha et al. 2007; Chen et al. 2002) have shown that a large portion of the network traffic is caused by massive duplicated downloads of the same popular content. For instance, top 10% of videos in YouTube account for about 80% of all the views (Chen et al. 2002). Thus, with this technique, by caching popular content at the edges (e.g., mobile devices and BSs) of mobile networks, the requested content can be closer to mobile users in the distance of the network topology, and mobile users can directly access the content cached at the edges instead of downloading the content from SPs over the Internet via backhaul networks. Reduplicated transmissions from servers to clients are avoided, and most of the requests from users can be satisfied immediately in mobile networks. Consequently, mobile edge caching can effectively enhance the network performances, especially on offloading network traffic (Chen and Yang 2016; Li et al. 2016, 2017), reducing system costs (Zhi et al. 2016; Gregori et al. 2016), and improving the quality of service (QoS) or quality of experience (QoE) of mobile users (Golrezaei et al. 2012; Zhao et al.

2016; Ao and Psounis 2015; Hong and Choi 2016; Li et al. 2015).

Another effective approach is to introduce the architecture of HetNets, which consists of different types of BSs (such as femto BSs, pico BSs, micro BSs, and macro BSs) with different wireless coverages (Li et al. 2016, 2017). HetNets can greatly enhance wireless link quality between mobile users and BSs and thus improve network capacity.

Considering the great potentials of the above two techniques, it is beneficial to combine them together, i.e., mobile edge caching in HetNets, which can effectively address the above discussed issues of MNOs. Studies in (Wang et al. 2015; Chen and Yang 2016; Zhi et al. 2016; Gregori et al. 2016; Golrezaei et al. 2012; Zhao et al. 2016; Ao and Psounis 2015; Hong and Choi 2016; Li et al. 2015) focused on single-tier caching in either mobile devices or BSs in mobile networks. Studies in (Li et al. 2016, 2017; Yang et al. 2016; Jiang et al. 2017; Xu and Tao 2017) focused on hierarchical BS caching in HetNets, where the edge caching in mobile devices is not considered. Studies in (Rao et al. 2016; Wang et al. 2017) explored the mobile edge caching in both mobile devices and BSs in mobile networks.

Foundations

To satisfy content requests from mobile users, mobile edge caching in HetNets needs to consider two phases, i.e., content placement phase and content delivery phase.

In the content placement phase, mobile edge caching in HetNets mainly deals with the following four issues:

- **Caching Topology** – To bring content closer to mobile users, it is important to decide where to cache in mobile networks. In HetNets, content can be cached at the edges that consist of mobile devices and BSs, which can form an either single-tier or hierarchical edge caching topology. Firstly, MNOs need to design the network architecture of HetNets,

Mobile Edge Caching in HetNets, Fig. 1 An illustration of caching topology

especially about how many tiers or types of BSs there are in HetNets as well as how different BSs connect. Secondly, MNOs need to consider whether mobile devices are able to cache content or not. Thirdly, MNOs need to consider which tiers of BSs are able to cache content or not. As a result, the mobile edge caching topology can be achieved, denoting the deployment of caches at the edges of HetNets.

As illustrated in Fig. 1, the caching topology of mobile edge caching in a HetNet is hierarchical and consists of three tiers of caching, i.e., bottom tier with six mobile device caches, middle tier with four femto BS caches, and upper tier with one macro BS cache. Here, the HetNet consists of two tiers of BSs, i.e., four femto BSs and one macro BS. All the BSs and mobile devices are able to cache content. Besides, the connection among BSs, among mobile devices, and between BSs and mobile devices is via BS-BS links, D2D links, and cellular links, respectively. In particular, mobile devices are possible to be connected with any tier of BSs. For instance, mobile device 3 is connected with femto BS 1 and femto BS 3 at the middle tier as well as the macro BS at the upper tier.

- **Content cacheability and storage format** – Mobile edge caching in HetNets aims to achieve a trade-off between network performances (e.g., network traffic load, system costs, and QoS/QoE) that are usually expensive to be improved and storage costs that are becoming much cheaper. However, the practical scale of content owned by SPs is growing rapidly, and thus it is impossible to cache all the content. Thus, it is important to decide what content to cache (i.e., content cacheability) taking content popularity into account. As practically captured in (Cha et al. 2007; Chen et al. 2002), only a small amount of popular content accounts for a large portion of content requests from mobile users, while a long tail of content remains unpopular. Besides, different types of content have different cacheability (Wang et al. 2015). For instance, among the content types, videos and photos have the highest revisit rate. Moreover, a large content file can be chunked into a series of original segments, and original segments can be encoded into an arbitrary number of packets to explore the diversity of cached content, while a given number of different coded packets can be collected together and decoded into the original segments for recovering the content file (Golrezaei et al. 2012; Yang et al. 2016). Thus, a content file can be cached by storing in three formats: (1) entire original content in a neither unchunked nor uncoded case, (2) original segments in a chunked but uncoded case, and (3) coded packets from the original segments in a chunked and coded case.
- **Caching policy** – Caching policies, deciding what to cache, how to cache, and when to release caches for what network objectives, are crucial to achieve the performance gains

of mobile edge caching. In particular, the optimization objectives of mobile edge caching in HetNets can be various for enhancing network performances, such as offloading network traffic, reducing system costs, improving mobile users' QoS/QoE, and so on. It is also important to estimate the gain of caching a content file by evaluating its current popularity, potential popularity, storage size, and locations of existing replicas in the network topology based on the system learning and analysis from mobile users' social behaviors and preferences (Li et al. 2016, 2017). Mobile edge caching policies can be operated in offline/online manners based on the practical network requirements. Offline caching (i.e., proactive) is relatively static with some prior network knowledge such as content requests and content popularity, while online caching (i.e., reactive caching) is relatively flexible according to the dynamics of network knowledge. Rather than employing traditional caching policies (e.g., least recently used (LRU), least frequently used (LFU), and first-in first-out (FIFO)), it is important and challenging to design proper cooperative mobile edge caching policies in HetNets to improve the network performances.

- **Operation time of caching** – According to the change of content popularity and operated manners of mobile edge caching, different types of content can be cached in different time periods. Online caching needs to cache content immediately or in a short time, while offline caching does not. For instance, in offline caching, short-lifetime popular news with short videos are updated every a few hours, while long-lifetime new movies and new music videos are, respectively, posted weekly and monthly (Li et al. 2017). In order to reduce the traffic load and avoid possible network traffic congestion especially in busy hours, content can be cached in off-peak hours (e.g., late night).

In the content delivery phase, each mobile user requests content based on its own preference. In

order to satisfy a user's content request, mobile edge caching in HetNets mainly deals with the following two issues:

- **Content request routing** – Content request routing shows the possible routes for delivering the requested content in the derived caching topology to a user before operating practical wireless transmissions of content in HetNets. Specifically, in the network, the whole process of content request routing can be summarized as:
 - If a user's requested content is locally cached in its mobile device, then the request can be satisfied locally.
 - Otherwise, the user can first find the content in caches of other users in close proximity and then establishes a device-to-device (D2D) link with a user where the content is available and finally fetches the content in a D2D manner (e.g., Wi-Fi Direct, or Bluetooth) (Gregori et al. 2016; Rao et al. 2016).
 - If not yet satisfied, the user has to be served by the associated BSs via cellular links. If the requested content is locally cached, then the associated BSs satisfy the request directly; otherwise, the associated BSs need to explore the cooperation possibility for fetching the content from other BSs where the content is available.
 - If not yet satisfied, then downloading the content directly from SPs over the Internet via backhaul networks is the last resort.
- **Wireless transmission of content** – After the content request routing is known, the requested content will be delivered to mobile users with wireless transmissions via either D2D links or cellular links. In terms of D2D links, they are established only when a pair of mobile users are in close proximity and willing to share the cached content in a D2D manner. Here, social behaviors and content preference of mobile users need to be analyzed and estimated in advance by system learning. In terms of cellular links, the associated BSs with noncooperation or

cooperation can transmit the requested content to the user by unicasting/multicasting based on the practical data transmission schemes in HetNets. In particular, resource allocation and scheduling for wireless transmissions of content via cellular links is necessary to enhance the network performances while satisfying the content requests.

Key Applications

The technique of mobile edge caching in HetNets can be utilized for general MNOs to deal with the explosive growth in content requests from mobile users, and thus there are also vendors that are manufacturing cache-enabled base station products, e.g., cache-enabled femtocell products and cache-enabled Wi-Fi routers. For companies of content delivery networks (CDNs), a new key trend is also the extension of their services into mobile edge networks, particularly for BSs with opened interfaces for MNOs and third-party content providers. Mobile edge caching in HetNets can also be utilized in 4G networks, but will be widely deployed in 5G networks.

Future Directions

From the evolution of mobile edge caching in HetNets, it appears that, in the future, emphasis will be given on the following research directions as follows:

- Big data-based large-scale online/offline optimization of content caching for MNOs
- Machine learning-based analysis and prediction on mobile users' social behaviors and preference for caching and prefetching optimization
- More rapid and secure collaborations among mobile devices and BSs in HetNets
- Pricing methodology for mobile edge caching in HetNets

Definition

Mobile edge computing (MEC) has been proposed in recent years for offloading computation tasks from user equipment (UE) to the network edge to break hardware limitations and resource constraints at UE. Through migrating the computation, storage, and servicing capability to the

edge of network, MEC can deploy application, service, and content locally in a distributed way. To a certain extent, it will satisfy the critical low latency and high reliability requirements for future eMBB, uRLLC, mMTC scenarios.

Historical Background

The European Telecommunications Standards Institute (ETSI) proposed mobile edge computing (MEC) in 2014, which is a technology based on 5G evolution architecture and deeply integrates the base station (BS) and Internet services. This technology is highly concerned by operators and equipment vendors, i.e., Huawei conducted joint tests with major operators and believes that MEC is one of the key technologies for coordinating user needs and network capabilities, which will help customers to achieve the goal of intelligent manufacturing, such as production, maintenance, management, inspection, and security. In 2016, the Edge Computing Consortium (ECC) was formally established, which would further promote the development of MEC technology.

At present, researches on MEC mainly focus on the computing offloading, energy efficiency, edge storage, low-latency guarantee, etc.

Computing offloading means that the terminal device with limited computing capability transmits the heavy computing task to the nearby MEC servers, and the MEC server replaces the terminal to complete the computing task. After the computing task is over, the MEC server returns the result to the terminal device. Chen et al. (2016) proposed a game theoretic approach for the computation offloading decision making problem among multiple-users in multichannel environments. To solve the problem of computing offloading in the Internet of Vehicles, Zhang et al. (2016) proposed a cloud-based mobile edge computing offloading architecture and designed an efficient allocation schedule of computing resources. Under the latency constraints of computing tasks, the resource utilization can be improved. Swaroop Nunna et al. (2015) proposed the concept of constructing next-generation collaborative architecture based on

MEC server under 5G network. It is located at the edge of mobile network and cooperates with the underlying communication network, which provides a potential architecture solution for the environment-aware collaboration of critical mission. Jararweh et al. (2016) proposed a software-defined system based on edge computing (SDMEC). Through the collaborative work of SD-Network, SD-Compute, SD-Storage, and SD-Security, the capabilities of cloud are expanded to the edge of the network, which satisfied the requirements of some applications, i.e., traffic regulation, content sharing, mobile gaming, etc.

In the view of the bright prospects of MEC, academics and industries have already carried out research on edge computing and have made some progress. However, the MEC technology is still immature, and specific implementation plans and related technical standards are still evolving.

Foundations

MEC offers application developers and content providers cloud-computing capabilities and an IT service environment at the edge of the network, as Fig. 1 shows. Through migrating the services which requires high complexity and high-energy consumption to the MEC server, the smart mobile terminals could solve the problem of limited capability in computation, storage, and battery. In additional, MEC can effectively reduce the demand of network bandwidth and the increasing transmission pressure of the core network with local offloading, caching, and deployment. To satisfy the future requirements of eMBB (enhanced mobile broadband), uRLLC (ultra-reliable low-latency communication), and mMTC (massive machine type communication), the following key technologies under MEC have been studied:

Traffic offloading. Traffic offloading is one of the basic features in the MEC. By leading a part of traffic to local network (campus network or enterprise network), traffic offloading can greatly reduce the stress of core network bandwidth and decrease the transmission delay.

The future network will be a merging network, which includes 4G, 5G, Wi-Fi, etc. Therefore, the future deployment of applications need to consider how to realize the local traffic offloading technology based on MEC in 4G networks. In addition, the development of the local traffic offloading technology in MEC needs to further clarify the commercial model.

Cache and acceleration. MEC can deploy the content closer to the end user. Thus, data can be directly obtained from local server, which would greatly reduce the service access delay. Besides, several questions need to be considered when caching is used in MEC:

1. According to the MEC typical service scenarios, and the existing caching models (local DNS, redirection, transparent proxy), MEC needs to choose appropriate caching model.
2. MEC needs to design efficient algorithm to optimize the cache performance or make a trade-off between its deployment place and the hitting ratio.
3. Cache channel from MEC to remote server needs to be optimized to support cache acceleration scheme based on MEC.
4. To avoid the same video content repeatedly download due to different resolution (different bit rate), MEC needs to consider how to cache the same video content (HD) version and regenerate the content for different resolution (rate) to provide service for different kinds of terminals.

Mobility management. Under the MEC environment, to provide service continuity, new mobility management needs to be deployed at the edge of the network. The mobility management is expected to handle three scenarios including the change of data forwarding path caused by UE mobility, application data migration due to load balance, and interaction between MEC system and other systems when the UE moves in/out MEC service area.

MEC-based computing offloading. MEC-based computation offloading is a technology which leverages the edge devices near terminals to process task. By using a series of network

Mobile Edge Computing: Low Latency and High Reliability, Fig. 1 The architecture of MEC

equipment near the BS, the delay sensitive service should be offloaded to the edge devices for rapidly response and lower latency. Moreover, besides eMBB scenario, the 5G network contains lots of low-latency high-reliability services, such as V2X, intelligent manufacturing, etc. These applications require many sensors or terminals for information collection, then transmit the information to the network side for cooperative process. Although the computing capability of single edge device is finite, the network has large number of edge devices which means the distributed computing can be used in this scenario. Therefore, the computing capacity of all the edge devices could be combined, which could form a distributed edge computing pool to remarkably reduce the computing pressure of cloud platform, ensure the QoS of communication, and improve the stability and reliability of the network.

MEC security. The MEC server is a brand-new type entity in the mobile network. While connecting to several mobile network entities including Operation Administration and Maintenance (OAM) system or Lawful Interception, etc., it also connects to the third-party application server and even accommodates the third-party application. It is noted that current security techniques including IP sec, TLS, firewall, etc. could secure these connections to block the attack to the MEC server, mobile system, and the third-party server. However, these solutions are not

safe enough for the new security issues with the introduction of MEC. It is necessary to setup a unified, credible security evaluation system to evaluate the security of the applications running in the MEC system, which will only guarantee the trustable third-party application in the server. Meanwhile, the security aspects of the interface between the application and the network should also be considered for safely communication, e.g., the unauthorized invocation. There are also new business opportunities for operators to provide the security service. The mobile operator could provide the service to shield the application in the MEC server from the malicious attack and check the security bugs of the third-party apps.

Key Applications

According to the definition of the ETSI Industry Specification Group (ISG), MEC offers application developers and content providers cloud-computing capabilities and an IT service environment at the edge of the network. This makes it possible to deploy the application, service, and content closer to the UE in a distributed manner. The MEC application focuses on the scenarios of low latency and high bandwidth. According to different service characteristics, the MEC applications can be divided into the following two categories: local service and vertical industry. The local service

applications mainly consist of campus network and AR/VR service, etc. And the vertical industry applications mainly include the V2X and industrial Internet scenarios. The following are some typical applications of the local service and vertical industry applications.

Local Service

Typical Application 1: Local Video Surveillance

In the scenario of local video surveillance, the traffic volume of video surveillance especially HD video is very huge. For example, the uplink bandwidth is up to 16Mbps for 4K HD video. If all data must be sent to the central cloud, it will consume large backhaul bandwidth. On the other hand, the video needs to be processed and analyzed timely to handle the emergency situation. The MEC can satisfy the user requirement by offloading the traffic and processing the data locally to provide a better user experience. Besides video surveillance, many applications like sports event live require low latency and high bandwidth, and MEC can significantly enhance the user experience and reduce the operator network load in such environment.

Typical Application 2: Augmented Reality

There exist many scenarios for AR, such as museum, city memorial, sports event, and concert, which can enhance the user experience remarkably. MEC can achieve efficient office automation assistance, local resource access, and internal communication in these applications and can provide the consumer better experience and the ability to access local service.

Vertical Industry

Typical Application 1: Autonomous Driving

The autonomous driving vehicles generate large amounts of data. For example, one autonomous driving vehicle can generate and process TB level data per hour, which requires high bandwidth for data delivery and needs immediate processing the data and delivers the result to the vehicles with ultra-low latency. The latency requirement for assistant driving is 20-100 ms,

but autonomous driving requires 3 ms. MEC is one of the technologies for realizing low-latency traffic in mobile networks. There are two types of MEC deployments for Internet of Vehicles (IoV). The first one needs building an edge cloud system at the base station side, and the other one uses strong computing capability BS to provide low-latency services for mobile terminals.

Typical Application 2: Industrial Internet

Industry Internet of Things (IIoT) enables intelligent manufacturing for future industry, whose production data would be generated locally. The data processing and the result feedback need ultra-low latency which may be lower than 1 ms. Thus, the processing and computing can only be finished locally due to the privacy requirement. MEC can satisfy this requirement, which can also complete the coordination of different production processes, such as Drone and Robot.

Further Directions

MEC is a new network architecture concept, which has many new features comparing to the existing 3G/4G cellular systems with better latency and reliability performance. Therefore, there are many research challenges and opportunities in the future research works. The security of the MEC, the integration of the computing, storage and communications in the MEC architecture, the online caching in the MEC, etc. should be further researched.

Mobile IP

Charles Perkins
Huawei Technologies, Santa Clara, CA, USA

Synonyms

MIP; MIPv4; MIPv6

Definition

Mobile IP (MIP) is a mobility management protocol developed within the IETF (Perkins 2002; Perkins et al. 2011). It is often also used to refer to one of, or a suite of, related protocols such as Proxy MIP, Mobile IPv6, Hierarchical Mobile IP, Fast Mobile IP, and numerous extensions for these.

Historical Background

The development of Mobile IP started in the early 1990s following on work done at Columbia University, IBM T.J. Watson Research, Carnegie Mellon University, and a number of other research groups. Further development

has continued in research departments around the world for many years, investigating the effects of Mobile IP on TCP, performance under high packet loss, hierarchical routing schemes, distributed mobility, interactions with BGP, etc.

The main problem solved by Mobile IP was to loosen IP's tight binding between the identity and the location of a mobile device. Since the beginning of the Internet, network-addressable devices had been known as stationary computers, and so routing data to the computer running an application really amounted to using routing prefix of the IP address to locate the network on which the computer was located. Put another way, once data arrived at the location determined by the IP address, there was not any question about the identity of the networked computer that would receive it. With the arrival of smaller mobile computers in the late 1980s, this assumption was no longer valid.

Protocol Operation

Mobile IP solves this problem by associating two IP addresses with a mobile device. One is the locator, and this IP address changes when the device moves to a new network. The other IP address is the device's identity, which does not change. The protocol itself is designed as an extension to IP, which binds (associates) the two IP addresses at a router on the device's "home network." The home network is the network to which data will be routed based on the IP address which identifies the mobile device. Once data arrive there, the router on the home network instead routes the data to the IP address which is the locator of the mobile device. The router that does this is called the "home agent." The locator IP address is routable to the network (called the visited network) currently visited by the mobile device. The association between the identifying IP address and the locating IP address is called a "binding," and as the locator IP address changes, the binding changes to reflect the updated address.

The process of updating the binding is the central design point for Mobile IP – and, indeed,

Mobile IP, Fig. 1

a similar requirement exists for practically every mobility management protocol whether or not developed in the IETF. Naturally, there are many details. Binding updates have to be done securely, to prevent unauthorized network devices from binding the MN's identifier IP address to a false locator IP address. There are many ways to prevent unauthorized tampering with the true locator IP address, and this is an area of protocol design that is still evolving in the Internet today. Another design area is related to the mechanism by which the home agent redirects traffic from the home network to the current location of the mobile device. This usually involves tunneling (encapsulating) the data once it arrives at the home network by putting on a new IP header that will cause the data to be routed to the locator IP address.

Many tunneling protocols exist in the IETF, and probably every one of them could be used for the purpose of redirecting traffic from the identifier IP address to the locator IP address, which in Mobile IP documents is typically called the "care-of address." Moreover, it is also possible to insert into a data packet a "source route" which supplies a list of intermediate routing points that can be followed to ensure the ultimate delivery of the packet. Tunneling and source routing are more or less equivalent, but tunneling has had more design work in the IETF and so has generally been favored for redirecting traffic as with Mobile IP. Lately, however, source routing is receiving renewed interest in the IETF (check the segment routing WG Fig. 1).

In the figure, a mobile device (mobile@example.com) has established a point of attachment with the Internet by way of a local router. For the rest of this entry, the mobile

device will be called a mobile node, abbreviated MN, as is usually done in IETF documents. Any other Internet device that communicates with MN will be called a Correspondent Node (the name often used in Mobile IP documents for the other communication endpoint for some traffic to/from MN). Traffic from the Internet can reach the mobile node (MN) by arriving at the Home Network, where the packets will be redirected (tunneled) to the local router currently serving the mobile node.

As a general observation, mobility management systems universally require some way for packets to be redirected to the current point of attachment of a mobile node. Determining the address for the redirection requires a lookup operation somewhere in the Internet. For business reasons, wireless operators have demanded that this lookup operation occurs within the operator's network, but this is not mandated by Mobile IP. The exact architectural placement of the lookup operation has a crucial effect on the performance of mobility management. Mobile IP is unique among mobility management systems in that the lookup operation occurs naturally on the routing path of the traffic to the mobile node, as determined by the mobile node's home address. All other systems have to insert some architectural augmentation for this to happen, which can easily be the source of bugs, performance loss, and other problems.

Packets routed to and from MN, which are redirected from the home network, experience additional delay because of the longer routing path. Depending upon local requirements in the network visited by MN, it is also likely that packets from the mobile node will have to be tunneled back to the home network. However, if a

correspondent node is able to receive information about the IP address of the mobile node in the visited network, then that correspondent node can use the information to route packets directly to and from the visited network. Any method by which the correspondent node is able to obtain the mobile node's care-of address is a kind of route optimization; various such methods have been proposed for MIPv4 and MIPv6.

Mobile IP for IPv4 (MIPv4) (Perkins 2002) and Mobile IP for IPv6 (MIPv6) (Perkins et al. 2011) are very similar in general operation, but there are important differences. The first distinction is that MIPv4 specifies the behavior of the local router, which for MIPv4 is called a Foreign Agent (FA). The Foreign Agent can issue periodic beacons to notify mobile devices that the FA is offering mobility services, and also provide a local IP address (i.e., a locator IP address). Once the mobile device MN identifies a Foreign Agent, then MN can use a (topologically correct) locator IP address as the local endpoint for traffic which will be tunneled from the Home Network. Thus, equipped MN supplies the locator IP address to the Home Agent and instructs the Home Agent to intercept traffic destined for the MN. If the tunnel is established between the Home Agent and the Foreign Agent, then the FA decapsulates packets and delivers them to the MN. Otherwise, the tunnel can be established between the Home Agent directly with the MN, and the FA has only to route the encapsulated packets as usual.

MIPv6, on the other hand, does not need to specify a Foreign Agent. By the design of IPv6, MN can get a locator IP address either by way of Router Advertisement or by way of DHCP (depending on local network administrative requirements); local IPv6 routers can be expected to support DHCP. Also, MIPv6 enables a special kind of routing header that causes packets to be delivered to MN's care-of address, avoiding the extra overhead of IPv6-within-IPv6 encapsulation.

As noted above, binding updates have to be performed securely. When Mobile IPv4 was designed, there was no IPsec. As a result, various Mobile IPv4-specific mechanisms were designed. These are still in use with MIPv4 and have

not been reported as broken or suffering from vulnerabilities that have plagued many other security protocols. The mip4 working group of the IETF even designed a key management and allocation protocol which enabled establishment of session keys for mobility management, based on an underlying security association between the home agent and the mobile node.

The security design of Mobile IPv6 was largely designed to utilize IPv6's security design (IPsec). IPsec offers authentication by insertion of a specially encrypted signature to guarantee that tampering can be detected. For further privacy, IPsec also offers payload encryption although this is not demanded for the safety of Mobile IPv6 signaling. Key management and refresh is also handled by standard IPsec methods.

Related Protocols

PMIP: At the time that Mobile IP was designed (late 1980s and early 1990s), IPv6 did not exist, and telecommunications was often considered synonymous with the international telephone system. Internet communication systems were mainly built on Unix systems running TCP/IP, and voice-over-IP (VOIP) did not exist for all practical purposes. In fact, VOIP was made illegal in some countries. As a consequence, the Internet was a small fraction of the total volume of communications. Internet applications typically did not have real-time requirements and ran on devices that did not move. As a further consequence, Mobile IP was not offered by the operating systems of the time that were dominant on laptop computers, which were the only ones that could move (albeit slowly). As the importance of Internet communications grew, network operators preferred to manage mobile devices without updating them to run Mobile IP. Instead, a network-proxy approach was desired which would restrict mobility management to the domain of a particular operator and still allow devices to be mobile within that domain even though the mobile devices did not have Mobile

IP available. This proxy approach is called Proxy Mobile IP (PMIP) (Gundavelli et al. 2008).

HMIP: An important variation of Mobile IP is “Hierarchical Mobile IP” (HMIP) (Soliman et al. 2008). HMIP was designed to separate the handling of local mobility (within one operator domain) from mobility between domains. The basic idea is to run local mobility management signaling to a local home agent as long as possible, and only transmit control messages to the (possibly distant) home network when the mobile device makes a new point of attachment outside of the domain which it had been visiting.

FMIP: A more sophisticated approach for reducing the latency penalty associated with mobility signaling across the larger Internet during handover has been designed and is known by the name of Fast Mobile IP (FMIP) (Koodli 2009). The basic idea is to enable neighboring IP access points to cooperate with each other by sharing information about the mobile node (MN). As MN moves from the network of one router (say, R1) to the network of another router (say, R2), R1 can send information to R2 about the mobile node, including its home address and its current locator IP address, temporary security credentials, multicast subscriptions, and other information (called “context”) about the mobile node to speed up the handover. Then, while packets in flight are still arriving at router R1, those packets can be further redirected to R2, the router serving MN at its new point of attachment. The signaling between the routers exchanges the context and sets up the temporary tunnel between the routers. The tunnel is configured to remain active for a long enough time so that the home agent can update its binding for MN to reflect the locator IP address associated with R2’s network.

Route optimization: As mentioned previously, route optimization techniques have been investigated for Mobile IP, so that a mobile node’s packets could be exchanged directly with a correspondent node without traveling to and from the home agent. One of the important contributions of Mobile IPv6 was to integrate a route optimization mechanism directly with the base protocol (Arkko et al. 2007). The route optimization protocol messages have the simple goal of

establishing a binding (as before, an association between the MN’s home address and its care-of address) at the correspondent node that can be used for tunneling. Then the correspondent node can use that binding to deliver packets directly to the mobile node’s care-of address. This was ground-breaking because it was the first time that a secure operation was designed to work across such a potentially large population of Internet devices (namely, the many possible correspondent nodes that might interact with a mobile node). The observation that enabled such a scalable approach to security was that the binding update can be authorized by assuring that the new care-of address belongs to the same mobile node with which a correspondent node had already been exchanging packets. This is a significantly weaker requirement than verifying the identity of a mobile node, and yet perfectly strong enough to prevent hijacking the mobile node’s traffic with its correspondent node.

Future Directions

Mobile IP and its related protocols have provided many innovations and a scalable approach to wide-area mobility management in the Internet. For various reasons, Mobile IP as specified within the IETF remains sparsely deployed in today’s wireless operator networks, but it has received a great deal of attention and has been influential in the evolution of modern telecommunication networks. With the advent of 5G networks, Mobile IP and its descendants within the [dmm] working group are seen as viable candidates for some 5G mobility management needs. With multigigabit wireless technologies already available, the high speed and architectural simplicity of Mobile IP become more attractive, as well as its inherent ability to serve all applications without requiring per-application mobility support.

Definitions

The protection of smartphones, tablets, other portable computing devices, and the networks

they connect to, from threats and vulnerabilities associated with wireless computing

Historical Background

Mobile security and privacy research has brought public attentions since the prevalence of cellphone and cellular networks. Notare et al. (1999) proposed a distributed security management system for telecommunications networks against cloned cellphones (same number and series of a genuine phone) in 1999. Thereafter, research in this area can be divided into two eras. The first era focuses on normal cellphones and voice services, such as cellphone authentication (Manabe et al. 2009), cellphone identification (Celiktutan et al. 2007), and cellphone cloning issue (Singh et al. 2007).

Since the debut of iPhone in 2007 and later the Android phones, research in mobile security and privacy is gradually shifting from cellphones to smartphones, which enriches more diverse application scenarios concentrating on mobile apps and mobile networks. The potential threats in mobiles may be caused by social engineering, compromised devices, malware, web browser or OS vulnerability, vulnerable application, and data interception. Especially, repackaging is one type of common attacks for smartphones targeting mobile apps, in which an attacker could modify a legitimate app to include malicious code and publish on third-party app stores. Correspondingly, the countermeasures have been developed to protect the mobile security and privacy, for example, multifactor authentication scheme that could avoid attacker easily guessing password or brute-force attack; detecting malware behaviors could play a significant role in reducing attack risks.

Different from traditional computer systems, the primary design objectives for mobile devices are low power consumption and portability. Hence, there are five key aspects of device- and application-level security features of mobile platform that distinguish mobile security from conventional computer security (La Polla et al. 2013): mobility, strong personalization, strong

connectivity, technology convergence, and reduced capabilities.

Mobile Vulnerability

- **Web-based services**

The mobile web is the most used platform other than mobile operating system (OS) platform. Similar to traditional web services on personal computers, mobile web applications that employ lightweight pages also suffer from security threats, such as phishing scams, drive-by downloads, browser exploits, cross-site scripting (XSS), SQL injection, etc. On the other hand, cyberattacks can exploit software vulnerabilities via mobile web browser to compromise mobile devices (Coursen 2007), such as PDF reader or image viewer.

- **Wireless networks**

Mobile devices can provide Internet connection and device-to-device communications at any time and in any place thanks to the wireless networks technologies, including Wi-Fi, cellular networks, Bluetooth, and near-field communication (NFC). Though these wireless networks provide convenience for users, using them in a public setting may cause potential risks. For example, Wi-Fi sniffing happens frequently with free Wi-Fi networks in airports, malls, and other public places when the mobile device is connecting to a malicious wireless access point (Beyah and Venkataraman 2011) and, hence, causes mobile devices' data exposure to attackers including account and personal information (Sujithra and Padmavathi 2012). Mobile networks may also suffer from overbilling attacks in which additional fees, such as fees of data traffic a user never used, are charged to the victim's accounts and transferred to the attacker's wallet.

- **Mobile malware**

As of the first quarter of 2018, more than 7 million of mobile apps are on the markets,

where Android users were able to choose between 3.8 million apps and Apple users can choose 2 million available apps in Apple App Store (Statista 2018). Among such huge mobile apps, there are many individual-developed third-party apps with malicious intent. Once those malicious apps, which may contain virus, Trojan, or botnet, are installed and gain access to the mobile devices, they could cause serious security breaches and incidents. As reported in Bradley (2011), more than 50 apps have been found to be infected by an Android malware called DroidDream in the official Google Play Store, which can stealthily gain root access to the device and further download additional malicious programs without user's knowledge and permission. As an example of smart malware, a multifarious malware for iOS devices, called iSAM (Damopoulos et al. 2011), has recently been designed, which integrates several typical malicious features of malware such as collecting confidential data stealthily and denial of application and network services, sending a large number of malicious SMS.

- **Weak authentication**

Most contemporary mobile devices use PIN, graphical pattern, or biometrics-based authentication such as fingerprint scan or face recognition. Those authentication methods are either vulnerable to malicious hacking, or the credentials are easily to be disclosed to others intentionally or voluntarily. PIN and pattern can suffer from *smudge attack* (Aviv et al. 2010), in which the password can be inferred by the smudge left on the screen surface when your fingertip touch on the screen. The brute-force attacks could be another threat to the PIN-based password. Though the biometrics-based authentication is superior because of the uniqueness of individuals, the biometric credentials are easy to be duplicated or counterfeited as anyone can obtain your fingerprint from a cup that you have hold.

What is even worse is that an attacker can obtain such biometric information from a distance. Chaos Computer Club announced that one of its members had been able to replicate the fingerprint of German Minister of Defense Ursula von der Leyen, using only photographs taken of her finger (CCC 2014).

Goal of Attacks

- **Denial of service**

Due to the portability and small-sized design, mobile devices usually have capability-limited hardware and battery, which restrict the computing, transmission, and power supply of the mobile device. Therefore, denial of service (DoS) attack is prone to target these shortages of mobile devices to disable one service, reduce the capability, or even make the whole device unusable by utilizing different attack techniques such as broadcasting highly malicious traffic stream, sending huge messages, or increasing power consumption. Battery power exhaustion attack is one of those DoS attacks that drains the battery faster than usual to forcefully shut down the device. The power of the device runs out up to 22 times faster than its normal condition by exploiting the wireless networks protocol vulnerabilities (Racic et al. 2006). The *water torture* attack (Johnston and Walker 2004) is another example of battery exhaustion attack carried out at the physical (PHY) layer that forces the device to send bogus frames. In addition, low-end mobile devices can be forced to shut down by receiving huge amount of SMS.

- **Privacy leakage**

Many mobile apps collect user data without users' permission such as address book or location information. A social media app was found to download users' full address books including names, phone numbers, and email addresses without users' knowledge or consent when enabling "find friends" feature. It is reported that mobile apps on

iPhone and iPad send personal information to advertising networks without the user consent too (Whitney 2010). Another most concerned privacy leakage is the location-related information. With the social networks apps becoming prevalent in our daily life, location-specific content have become more accessible and personalized to users' own context. Location tracking attack refers to attacker attempts to reveal the mobile device's location over time through examining their communications or hacking GPS information. Furthermore, if the business information is stored on the device, such invasions not only hurt the user's privacy but also increase the likelihood of security compromise to enterprise security.

- **Sniffing sensor information**

Comparing to traditional cellphones that are mainly used for communications, modern smartphone is a sensor-rich device that can provide extended functions equipped with multiple sensors, e.g., camera, microphone, GPS, inertial motion unit (IMU), compass, step recorder, etc. Once the attacker can access those sensors without authorization, all the user's actions will be sniffed and recorded. The stealthy video capture spyware can secretly start the built-in camera to record the private video, and it consumes little power that will not draw any attention from the user (Xu et al. 2009). Another example of compromised sensor is the microphone; *Soundcomber* (Schlegel et al. 2011) managed to extract private data, such as the touch sound of PIN or phone number, from the microphone.

M

Secure Protection Guidelines

- **Advanced authentication**

One-time validation of a user's identity, referred to as static authentication, has shown its vulnerability to attacks. Specifically, malicious adversaries may access the mobile

device that has been logged in by an authentic user when the authentic user is not nearby. Continuous authentication represents a new security mechanism which continuously monitors the user's trait and uses it as a basis to reauthenticate periodically throughout the login session. Hence, it has been adopted to overcome the limitations of traditional static authentication. These continuously monitored traits include typing habit and hand morphology (Feng et al. 2013), graphic touch gesture feature (Zhao et al. 2013), and cardiac motion and geometric information (Lin et al. 2017). Multifactor authentication is another alternative approach to enhance the security of the single trait authentication, which offers multifactor protections in case one credential has been compromised. For example, a set of behavioral biometrics of micro-movements and orientation patterns during hand movement, orientation, and grasp has been proposed for mobile authentication (Sitová et al. 2016). Controls such as one-time passwords, grid-based authentication, and digital-certificate-based authentication schemes can also help augment existing security solutions.

- **Malware detection**

To protect our mobile devices, it is essential to detect the mobile malware and illegal activities including anomaly, misuse, or specification-based system. Basically, there are two kinds of detection techniques as static analysis and dynamic analysis. In static analysis, malicious codes are detected by unpacking and decompiling the application. "DroidMOSS" developed by Zhou et al. (2012) could generate fingerprint for an application and perform similarity test for two "same" apps; then DroidMOSS made sure the application is not affected or repacked with malware to avoid application-based threats on mobile devices, while the dynamic analysis identified the malicious behaviors by running the application on an emulator or a device.

For example, monitoring power consumption is an easy way to detect whether malware are on your smartphone. Since the detection and analysis tasks utilize heavy resources of mobile devices, some of these tasks can be moved to the cloud for processing in the future.

- **Application development guidelines**

The awareness of secure programming guidelines is vital to the secure application development by preventing the occurrence of common errors in programming. Some useful guidelines include performing secure logging and error handling; following the principle of least privilege; validating input data; implementing secure data storage; and avoiding insecure mobile OS features, etc. (Jain and Shanbhag 2012).

- **Hardware-associated protection**

Hardware-associated protection implements a trusted execution environment by designing a hardware-enforced isolated execution environment for security-critical code, which provides protective mechanism in storing and processing sensitive data (Zhang et al. 2016). Techniques such as secure and authenticated boot (Ekberg et al. 2013) are employed to maintain a root of trust on the device. The most popular approach for mobiles is TrustOTP (trust one-time passwords) (Sun et al. 2015) that builds upon the ARM's TrustZone (Brasser et al. 2016) technology. Because it is a hardware-based protection, TrustOTP can prevent attacks that are in the mobile OS and even works when the mobile OS crashes.

Definitions

Mobility management in cellular networks is a set of functions that the network uses to keep track of the location and status of the mobile device and to provide proper service to the mobile users.

Historical Background

Mobility management in cellular networks is a set of functions that the network uses to keep track of the location and status of the mobile device and to provide proper service to the mobile users. In the cellular networks, mobile user equipment (UE) may move around whole network coverage, and it is expected that both Mobile Terminated (MT) and Mobile Oriented (MO) services are provided regardless of UE location and movement. Therefore, mobility management is one of the major functions in the cellular networks. Mobility management in cellular networks generally includes user equipment (UE) registration to the network, UE location tracking, paging to enable mobile terminated communication, support of handover, and so on. Additionally, in a wide sense, mobility management also includes the functions to support session continuity during

user mobility, e.g., IP address allocation, traffic anchoring, tunneling, and so on. The earlier generations of 3GPP cellular networks, including 3GPP LTE system, have supported the mobility management function (3GPP 2017a). 3GPP 5G network also supports the mobility management functions similar to the ones supported in 3GPP LTE system with some enhancements as specified in 3GPP (2017b,c,d,e). This article summarizes the mobility management in 3GPP 5G network.

Key Mobility Management Functions in 5G Network

User State Management

In the cellular network, which mobility management functions and procedures are applied to a mobile user depend on state of the user. Three types of states are defined in the 5G system, i.e., Registration Management (RM) state, Connection Management (CM) state, and Radio Resource Control (RRC) state. RM and CM states are managed by the core network. The RM state represents whether a UE is registered in the 5G Core Network (CN), and the CM state shows whether Non-Access Stratum (NAS) signaling connection between UE and 5G CN is established. On the other hand, RRC state is managed by Radio Access Network (RAN), and it represents whether a connection between UE and 5G RAN exists or not. A UE in the RRC-CONNECTED state is in CM-CONNECTED state, and a UE in the RRC-IDLE state is in CM-IDLE state except during the transient phase, because radio link connection is required to establish NAS signaling connection to the core network (Figs. 1 and 2).

RRC-INACTIVE state is newly introduced in the RRC state model. The new state is proposed to be used as a primary sleeping state prior to RRC-IDLE state. When a UE moves to the new state, both the UE and RAN keep the context information of the UE's RRC connection, such as UE capabilities and security context, though the active radio link between the UE and RAN is released. The new state enables a lightweight transition from inactive to active

Mobility Management in 5G, Fig. 1 RM state model in 5G system

Mobility Management in 5G, Fig. 2 CM state model in 5G system

data transmission. A UE in the RRC-INACTIVE state is in CM-CONNECTED state except during transient phase. The 5G CN is not aware of the UE transitions between CM-CONNECTED with RRC-CONNECTED and CM-CONNECTED with RRC-INACTIVE state.

Handover and Cell Reselection

The choice of mobility procedure when the user moves to the coverage of other cell depends on RRC state of the user. The mobile UE in RRC-CONNECTED state uses a network-triggered procedure called handover for cell change, while mobile users in RRC-IDLE state or RRC-INACTIVE state uses a mobile-triggered procedure called cell reselection for cell change.

For the UE in RRC-CONNECTED state, Radio Access Network monitors the signal strength/quality from multiple cells to a user based on measurement report from the user and decides to trigger handover to serve the mobile user in a better cell. RAN and core network is aware of the UE mobility event and UE location after handover.

In the RRC-IDLE state or RRC-INACTIVE state where the user does not maintain active connection with RAN, the UE decides whether to camp on the current cell or to reselect a neigh-

boring target cell based on signal strength measurements without interaction with the network. Therefore, the network may not be aware of the mobility event and exact location of the UE after cell reselection. Therefore, specific UE location tracking mechanisms are needed for the UEs in RRC-IDLE state or RRC-INACTIVE state, and they are described in the next section.

UE Location Tracking and Paging

UE location tracking is responsible for detecting whether the UE is reachable and providing UE location for the network to reach the UE. In most cellular networks, the location update procedure, which allows a mobile device to inform the cellular network when it moves from one location area to the next area, is used as the basic mechanism for location tracking of idle UEs, e.g., Tracking Area Update procedure in 3GPP LTE network. 5G network also supports such location update procedures.

In the 5G network, such functions can be located either at 5G CN (in case of RRC-IDLE state) or 5G RAN (in case of RRC-INACTIVE state). When a UE registers with the network, the network allocates a set of Tracking Areas (TAs) as a registration area of the UE. Each TA is composed of one or multiple cells, and each cell broadcasts the TA which the cell is

contained in. The UE in RRC-IDLE state moving to a new cell checks whether the new cell is still contained in the current registration area based on the broadcasted information. The idle UE triggers a registration update procedure only if the new cell is not contained in the current registration area. Accordingly, 5G (core) network keeps track of the location of UE in RRC-IDLE state in a registration area level.

In 5G system, RAN also needs to support the location tracking for the UE in RRC-INACTIVE state. In that state, RAN needs a new location tracking functionality to detect the location of the UE because the connection between the UE and the RAN is not active. RAN allocates RAN notification area, which is composed of multiple cells, to a UE, and the UE in RRC-INACTIVE state triggers a RAN notification area update procedure only if the new cell is not contained in the current RAN notification area. 5G (radio access) network keeps track of the location of UE in RRC-INACTIVE state in a RAN notification area level.

When downlink traffic arrives and the UE is in RRC-IDLE state or in RRC-INACTIVE state, the network (CN or RAN) triggers paging procedures with the consideration of the UE's expected location obtained by the UE location tracking procedures. Then, the UE which detected the paging message sends response to the network, and network gets to know the exact location of the UE, i.e., the current serving cell. The network provides the mobile terminated service to the detected UE location.

Dynamic Mobility Policy Enforcement

Policy Control and Charging (PCC) framework defined in the earlier generation of 3GPP system enables dynamic policy enforcement. In PCC framework of 3GPP LTE system, only session and QoS-related policies are supported. On the other hand, 5G PCC framework also supports mobility policy enforcement. Policy Control Function (PCF), which is the network function mainly managing the policy, can direct interact with AMF, which is the network function managing UE mobility, to support mobility-related policy enforcement. The mobility policy includes Service Area Restrictions and RAT/Frequency Selection Priority.

Support of Session and Service Continuity

Providing session and service continuity of an active session for mobile user is one of the most important tasks of cellular networks. To support session continuity, 5G system provides session anchoring in the gateway and tunneling (tunnel generation and update to the new RAN node on UE mobility) between the anchoring gateway and RAN node like the earlier generation of cellular networks. In 5G system the anchoring gateway (such as P-GW in 4G) is referred to as PDU session anchor (PSA) User Plane Function (UPF). The PSA terminates the user plane in the 5G core network and interfaces with the data network. In case of IP type of session, IP address preservation is an important aspect of session and service continuity, so that the PDU session anchor

Mobility Management in 5G, Fig. 3 SSC mode in 5G system

is responsible for IP anchoring as P-GW does in the EPC.

The main enhancement on session and service continuity in 5G system is that the different levels of session and service continuity procedures can be used according to the characteristics of each session. In the LTE system, continuity of IP session for all UEs is guaranteed in the whole system area. That is, the P-GW and the IP address of UE's PDU session are maintained regardless of the location of the UE such that the session continuity is maintained. On the other hand, 5G system aims to provide various levels of session continuity depending on the type of UE and type of service by allocating different Session and Service Continuity mode (SSC mode) per PDU session.

Three types of SSC modes are defined in 3GPP 5G system, namely, SSC mode 1, SSC mode 2, and SSC mode 3. Separate SSC modes are closely related to how the PDU session anchor is allocated and managed. In SSC mode 1, session continuity is guaranteed in all areas by keeping the PSA identical regardless of access network type and UE location as in the LTE system. In SSC mode 2, the same PSA is maintained across only a subset of the whole network. The PSA of a PDU session may be released and reallocated based on some criteria, e.g., to be served by the better UPF considering the UE's new point of attachment to the network. Lastly, SSC mode 3 enables the UE to connect to a new PSA before the connection with the existing PSA is released, and hence, the UE can receive services from two PSAs at the same time. By using this mode, various optimization can be supported, e.g., a newly created flow is served by a new PSA located in a preferred location while maintaining the existing flows in the previous PSA to provide session continuity (Fig. 3).

Definition

Named Data Networking, as a clean-slate network model, is designed to support direct routing with content name in order to improve the security and efficiency for the future Internet. In NDN (Zhang et al. 2010), content such as a movie is divided into a set of individually named smaller content objects. Content object names are hierarchical and human-readable similar to the

Routing-Based Approach: In the routing-based approach (Han et al. 2014), two faces corresponding to before and after handover exist in each entry of the FIB. When a router receives an Interest packet, the mobility face (corresponding to the state after handover) of the FIB is firstly checked. After the MP moves, it sends an informing control message to its AR-H. Upon receiving the informing control message, the AR-H sends back an updating control message to update the FIBs along the path from the AR-H to the MP. In this way, the Interest packet can be forwarded to the current MP.

Locator/Identifier Split Approach: In the locator/identifier split approach (Hermans et al. 2012), a new field called Location Name is added to the Interest packets. When an NDN router receives an Interest packet, the Location Name is firstly searched in the FIB. After the MP moves, it sends the binding information to the AR-H, and then the binding information with the MP prefix and its AR-H prefix are recorded in the AR-H. When the AR-H receives an Interest packet that requires the MP's content, it puts the AR-F prefix in the Location Name of the Interest packet. In this way, the Interest packet with the Location Name is forwarded to the MP. The content can be cached with its original content name in the routers.

As stated above, the content name-based routing has no relationship with its location in NDN. Then the mobile consumer can reissue the Interests from the new location to support its mobility. However, how to use this "loose" routing scheme and on-path caching for efficient mobility management has a huge research space (Kim et al. 2012). Do-hyung Kim differentiated the real-time service and unreal-time service of NDN. Then a rendezvous point is deployed for the necessary location management for the mobile consumer (Lee et al. 2011). J. Lee and some other researchers proposed the proxy-based mobility management schemes for mobile consumer in NDN (Lee and Kim 2011; Oh et al. 2010; Wang et al. 2013), mainly to reduce the packet loss during the handover. The main operation can be illustrated as (1) after the consumer detects its

movement, it immediately sends "Hold request" message to its proxy. (2) When receiving the "Hold request" message, the proxy stops delivering data packets and only stores the data packets in its local repository for subsequent retransmissions. (3) When the mobile consumer acquires new location information, it notifies the location information to its proxy node with "Handover notification" message. Then the proxy node transmits the stored data packets to the new location of the mobile consumer.

However, in reality, it's normally required to support mobility management for both consumer and publisher with the same logic because a node may act as consumer and publisher simultaneously. Z. W. Yan proposed a distributed mobility management solution (Yan et al. 2016), which can well support both mobile consumer and mobile publisher and even their simultaneous mobility as shown in Fig. 2.

In this solution, a new singling message named as "Control" message is designed in order to probe the branching node on the paths before and after handover, and it contains necessary information to indicate the new access router and the pending content. Then the on-path routers from the branching node to the new access router will adjust the routing information (PIT for mobile consumer and FIB for mobile publisher) accordingly. In this way, the mobile consumer can get the data as soon as possible after the handover. Besides, the established states can be well used during the handover and then the protocol cost can be reduced. Similarly, the publisher mobility is also based on the branching node probing and hop-by-hop state update, and then the signaling cost caused by the routing flooding can be reduced significantly.

Key Applications

With the development of mobile Internet, more and more traditional networking services will be deployed in the mobile environment. For NDN, the mobile applications supported by the above-mentioned mobility management schemes may be deployed in everywhere, for example, smart

Mobility Management in NDN, Fig. 2 Distributed mobility management in NDN

transport, data dissemination in partially connected environments, collaborative sensing, and presence-aware services (Siris et al. 2012).

Future Directions

With the development of wireless communication technologies, such as 5G, more and more content will be produced and consumed in the high-speed wireless networks. NDN provides a solution to support efficient routing which totally de-couples the content identifier and its location. Then this distributed communication model asks for distributed mobility management scheme (Chan et al. 2014) to guarantee its efficiency and scalability.

ID/locator separation-based mobility management; ID/locator split-based mobility management; Mobility management with ID/locator split

Definition

Mobility management includes network functions that make mobile devices remain connected to the network despite their movement from one place to another, and making them reachable irrespective of their location. Mobility management includes two types of functions: location update and handover. Location update function maintains reachability of mobile devices irrespective of their location, and handover function maintains connectivity during the time when mobile devices detach from one network and attach to another.

ID/locator separation is a concept of using two distinct values (i.e., identifier and locator) for the representation of identity and location of a mobile device. IDs are used in the application and transport layers to identify the communication endpoints or session states, while locators are used in the network layer to denote the location of mobile devices by the routing system in the network topology. This concept is different from the original concept of the Internet, where an IP address is used as both ID and locator. Mobility management with ID/locator separation becomes easier than in conventional IP networks because the change of locators during mobility does not require changing IDs being used in the transport session states.

Historical Background

Mobility was not considered when designing the Internet about 40 years ago. It was assumed that the IP address of a device, host, or node (Note: device, host, and node are used interchangeably in this article) remained static during a communication session. The IP address has been used in the role of both identifiers and locators. Namely, the IP address is used in the network layer protocols as a locator to locate the device in the routing system and forward packets towards it. The same IP address is also used in the transport and application layers to identify the communication sessions or endpoints. Actually, this dual semantic of IP address is hindering the Internet from supporting mobility natively because when the mobile device moves, it has to change its IP address, resulting in terminating the session identified by the IP address.

To enable a mobile device continue its communication session even after moving from one network to another in the Internet, Mobile IP protocols have been developed and standardized by the Internet Engineering Task Force (IETF) in 2002 (for IP version 4, or IPv4) and in 2004 (for IP version 6, or IPv6). Mobile IP protocols allow mobile devices to possess two types of addresses: home address and care-of address. Home address is a persistent address obtained from the home network prefix and used in application and transport layers, whereas care-of address is obtained from a visiting or foreign network and used temporarily in the network layer as long as the mobile device resides in the visiting network. Mobile IP protocols are based on the concept of “map and encapsulate,” where the IP address, i.e., home address, existing in the IP header of packets destined to the home network is mapped with the care-of address by searching in a mapping table, and IP packets are encapsulated by another IP header containing the care-of address in the destination address field and forwarded to the mobile device’s current location.

Mobile IP protocols are complicated due to the necessity of maintaining home agents for managing up-to-date mapping between home addresses and care-of addresses and tunneling

packets. Mobility management with ID/locator separation can be simpler and more efficient because it allows a single ID to dynamically associate with various locators at the same time or different instances of time. It has the potential to natively support heterogeneous types of network-layer protocols and multihoming. These features enable to perform make-before-break or seamless handover easily without requiring any network-side anchor points and tunnel management.

Key Proposals

ID/locator separation-based network technologies and standards have recently been developed by IETF, which has published several RFCs on Host Identity Protocol (HIP), Locator ID Separation Protocol (LISP), and Identifier-Locator Network Protocol (ILNP). Similarly, research projects in various countries have also proposed ID/locator separation-based networking technologies, such as Heterogeneity Inclusion and Mobility Adaptation through Location ID Separation (HIMALIS) in Japan, Mobile Oriented Future Internet (MOFI) in Korea, and MobilityFirst in the USA. Since these proposals are based on the same concept of ID/locator separation, they have many common features, which are discussed next.

ID/locator separation-based architectures use nontopological values as the identifiers of mobile hosts. They use topologically significant values as locators to represent the location of mobile hosts in the network. The set of locator values associated with a host change when the host's connectivity in the Internet topology changes due to mobility; however, the identifier does not change. Dynamic bindings exist between identifiers and locators values, which are updated as locators change. The bindings are maintained inside the host as well as stored in a mapping service system such as the Domain Name System (DNS).

Figure 1 depicts a union of protocol stacks of all ID/locator split architectures mentioned above. This figure shows the existence of a new layer, which is often known as identity layer, between the transport and network layers in the

host and access gateway protocol stacks. The identity layer isolates the applications and transport layers from the underlying network layer and performs ID-to-locator mapping. Some proposals (such as ILNP and MOFI) do not explicitly mention about the existence of an independent identity layer, but assume similar functions existing in the network layer. In host-based ID/locator separation architectures (such as HIP), the identity layer exists only in the host protocol stack and in the network-based architectures (such as LISP), the identity layer functions exist in the access gateways only, while in the hybrid architectures (such as HIMALIS and MOFI) these functions do exist in both hosts and access gateways.

In ID/locator separation architectures, the application and transport layer protocols use IDs to represent communication endpoints and session states. IDs have end-to-end significance and they do not change due to mobility. On the other hand, locators are used in the network layer for routing and forwarding of packets. The locator values appear in the network header (i.e., IP header) of packets and may have only local significance and change as the packets pass through the access gateways. The set of locator values associated with a node also change when the node's connectivity in the Internet topology changes due to mobility; however, the identifier does not change, thus the transport and transport layers session states remain unchanged after mobility.

Mobility management with ID/locator separation requires involvement of the identity layer, the network layer, as well as the lower layers, when a mobile device moves from one network to another. The lower layers perform the lower-layer handoff functions such as detecting that the radio signal coming from a new network is getting stronger than that from the currently connected network and setting up radio channels and parameters for a new connection. Similarly, the network layer configures a new locator based on the addressing scheme used in the new network and notifies the identity layer about the new locator. The identity layer performs the location update signaling function to update the ID-to-locator mapping cached in the correspondent host

Mobility Management with ID/Locator Separation, Fig. 1 ID/locator protocol stack generic representation

and stored in the mapping server system. After the location update, ongoing communication sessions of the mobile host continue from the new network. Moreover, since ID/locator separation architectures naturally support multihoming by associating the same ID with multiple locators, the mobile host can momentarily be multihomed during the handover time by setting a new link and locator in the new network while still holding the link and locator from the old network. Seamless handover is easily achieved by having the mobile host perform location update in the correspondent host from the new network while still being connected with the old network.

These ID/locator separation-based architectures have some subtle differences in terms of the ID type and configuration methods, ID-to-locator mapping database system, and components handling mobility management functions. These are discussed next.

HIP

HIP architecture and protocol have been specified in RFCs 4423 and 7401, respectively. HIP prescribes to use public keys (and their hash values) as host IDs and IP addresses as locators. HIP extends the Domain Name System (DNS) records to store host IDs as a new resource record type. A host acquires its peer host's ID and locator by sending a domain name resolution request to a DNS server. After obtaining the ID and locator of a mobile host, the correspondent host initializes communication with the mobile host

by exchanging few control packets (known as Base Exchange). Both the source and destination hosts' IDs appear in the identity header and locators in the network header of control packets, while the subsequent data packets include IPsec header instead of the identity header.

For mobility management, HIP introduces rendezvous servers as the anchor points that store the current locators of mobile hosts. Rendezvous server's locators are registered in the DNS server as the mobile host's global locators. The first control packet of an incoming communication request from a correspondent host to the mobile host arrives at the rendezvous server and gets forwarded to the mobile host. The mobile host notifies the correspondent host by sending information about its current locator in the subsequent control packet so that the next packets sent from the correspondent host reach the mobile hosts directly, i.e., without requiring the rendezvous server in the path. On changing its locator due to mobility, the mobile host sends a location update signaling message to update the ID/locator mapping cache of the correspondent host as well as the rendezvous server. In this way, the mobile host can communicate from the new network as well as maintain its reachability by updating the ID/locator mapping stored in the rendezvous server.

ILNP

ILNP architecture has been specified in RFC 6740. It divides 128 bits long IPv6 address into

two 64 bits long parts. The lower 64 bits have been used as identifiers, while the higher 64 bits are used as locators. ILNP assumes that “well-behaved” applications that use FQDN or other nontopological identifiers at the application layer, rather than IP addresses or lower layer identifiers, will perceive no architectural difference between IP and ILNP. Moreover, the ILNP packet format in wire is similar to IP packets; thus, ILNP can operate without requiring ID/locator separation supporting access gateways. However, it assumes the existence of routers that make the routing and forwarding decision on the basis of only the upper 64-bits values of the destination IP address present in the packet header. ILNP also proposes to add new resource record types to DNS server to store the NID (i.e., 64 bits node identifier), L32 (i.e., 32 bits locator), and L64 (i.e., 64 bits locators).

ILNP does not introduce any anchor point for the mobility management. It rather makes the mobile host to perform locator update signaling with the correspondent host as soon as it detects that its locator value has changed. The mobile host is also expected to update its locator values stored in the DNS server. However, since the DNS updates take a longer time to propagate, the mobile host may be unreachable for a while from new correspondent hosts.

LISP

LISP has been specified in RFC 6830. It uses prefix aggregatable endpoint IDs (EIDs), which are also used as locators in the edge network. In the transit network, routing locators (RLOC) are used as locators. EIDs to RLOCs mapping takes place in Ingress and Egress Tunneling Routers (ITR/ETR) located at the border between the edge and transit networks. Both EIDs and RLOCs are syntactically identical to IP addresses; they are different in semantics of how they are used. EID-to-RLOC mapping records are maintained in an overlay network of mapping database, called LISP Alternate Logical Topology (LISP-ALT).

The application and transport layers use EIDs, which also appear in the IP header of packets dispatched from the host. When the packets reach the ITR, the destination EID value present in the

IP header is mapped with a related RLOC obtained from the LISP map server. The IP packets are then encapsulated with LISP header, UDP header, and outer IP header containing the RLOCs in source and destination address fields. When the LISP packets reach at the ETR, their encapsulating outer IP header, UDP header, and LISP header are removed and simply forwarded in the destination edge network by the inner IP header containing EIDs.

Since it also uses EIDs as local locators in edge networks, LISP does not provide host mobility support natively. To provide host-mobility, it proposes to make the LISP mobile host look like a LISP site and possess a lightweight version of the ITR/ETR functions. When the mobile host moves from one network to another, it receives a new RLOC and updates the ITRs that are encapsulating packets from correspondent hosts by using the previous mapping, as well as the map server. The mobile host may use one of the various methods such as by sending a solicit-map-request message or piggybacking mapping data to update the mapping. Nonetheless, LISP lacks the procedure to complete the mapping update process in a short time, thus does not guarantee smooth handover.

HIMALIS

HIMALIS architecture (Kafle and Inoue 2010; Kafle et al. 2014) has the protocol stack exactly as shown in Fig. 1. The identity layer exists in the end hosts as well as in the access gateways that connect the edge network with the transit network. The transit routers are simply IP routers. HIMALIS IDs are 128 bits values containing organizational prefix, scope, and version bits in the prefix.

In HIMALIS, the identity layer obtains mapping between IDs and locators from the mapping system consisting of Domain Name Registry (DNR) and Host Name Registry (HNR) through a name resolution process. That is, these registries are used to resolve hostnames to IDs and locators during a communication initialization phase. The HIMALIS packets contain the identity header along with the transport and network headers. The identity header contains the source

and destination IDs which do not change end-to-end, while the network layer contains the source and destination locators (i.e., IP address) that do change as the packet passes through the access gateway. Having said so, the network header containing the local IP addresses is valid only within the edge network. Thus, a HIMALIS host knows only the local IP addresses of its own and uses the gateway's local IP address as the destination IP address in the network header of outgoing packets. The packets are routed by using local IP addresses in the edge network. As the packets reach the access gateway, their network header is removed and ID present in the identity header is searched in the mapping table to find the corresponding global locators. These global locators are used in the new network header to be attached to the packet. These global locators are used by the core router to route packets in the transit network.

In the destination access gateway, the global IP header is removed and a new local IP header, containing the destination host's and the access gateway's local IP addresses in the destination and source addresses, respectively, is attached to the packet. The packets reach the destination host.

HIMALIS supports mobility across various types of network protocols and differently scoped IP addressing in the edge networks. For example, one edge network can use IPv4 local addressing scheme, while the other edge network can use IPv6 addressing scheme, yet the hosts located in these networks can communicate to each other as the local network protocols are translated by the access gateways. In this way, the application and transport layer functions and session states are completely isolated from the network layer so that changes of network layer protocols and IP address as the host moves from one network to another due to mobility would have no adverse impact on the application sessions if the network layer readdressing is performed instantly during movement. As the host moves to a new network and obtains a new locator from the new access gateway, it immediately performs location update with the correspondent host by sending a signaling message containing its global locator (i.e.,

locator of the new access gateway) so that the correspondent host starts forwarding packets to the new network. At the meantime, the mobile host also informs its previous access gateway about its new locator so that the previous access gateway forwards packets destined to the mobile host to the new access gateway. In this way, HIMALIS attempts to achieve lossless handover.

MOFI

The MOFI architecture (Kim et al. 2013) is designed with three functional features in consideration: global identifier and local locator, query-first data delivery, and distributed control of identifier-locator mapping. MOFI uses global host IDs and local or private IP addresses as locators, and mapping is stored in distributed hash-based ID-locator mapping registers. MOFI does not mention about an explicit identity layer, but divides the network layer into two sublayers: communication and delivery. The communication sublayer is responsible for end-to-end communication, and the delivery sublayer is responsible for routing and forwarding in the access and backbone networks. The communication sublayer performs signaling operation for the locator search from the mapping registers collocated with access gateways.

When the mobile host moves from an old access gateway to a new access gateway, it obtains a new locator. As in HIMALIS, the mobile host informs the new access gateway about the information of the old access gateway so that they establish a handover tunnel to forward packets from the old access gateway to the new access gateway. Then the mobile host sends a location update message to the correspondent host. The mapping registers are also updated with the new locator.

MobilityFirst

The MobilityFirst architecture (Raychaudhuri et al. 2012) focuses on making the network centered on mobility and trustworthiness. It has proposed a globally unique ID (GUID) namespace for network attached objects such as smartphones, people, a group of devices/people, content, or even context. GUIDs are formed from

public keys assigned by a name certification service to the objects. It also introduces a name-based service layer that uses the GUIDs to enable mobility-centric services while ensuring security and trustworthiness. It prescribes a hybrid name/address based routing scheme, employing a fast global name resolution service (GNRS) to dynamically bind the destination GUID to a set of network addresses or locators. Every packet includes GUID in its header so that network nodes can offer GUID-based redirection or late binding to network addresses. On mobility, network addresses do change while GUID remains the same. The change in GUID to address mapping is reflected in GNRS by a mapping update signaling process.

Future Directions

There are several issues related to the deployment of ID/locator separation-based mobility architectures. Among them, security, ID namespace, ID-to-locator mapping directory service, and interoperability with existing IP networks are briefly discussed below.

Security: ID/locator separation-based architectures are considered to enhance security features of mobile networks because they allow mobile devices to use topology-independent names or identifiers to be used in the representation of security context which remain valid despite changing the network layer addresses and locators. HIP, MobilityFirst, and HIMALIS have indicated security as the prominent feature of the new architectures.

ID namespace: Introduction of a network topology-independent IDs and their management is an important issue. Different proposals have considered different types of IDs such as public keys and their hash values (in HIP and MobilityFirst), lower 64-bits of IPv6 addresses (in ILNP), IP address blocks not advertised in BGP routers (in LISP and MOFI), and new IDs (in HIMALIS). A harmonized approach is yet to be initiated.

ID-to-locator mapping directory service: Secured and scalable ID-to-locator mapping

directory service that can provide the mappings in a very low latency while being able to keep the mapping records up-to-date despite frequent changes in locators triggered by mobility is a challenging issue. Different proposals have considered different approaches to maintain the mapping directory service, such as HIP extends DNS records and introduces rendezvous servers, LISP specifies the LISP-ALT, and HIMALIS proposes to use HNRs.

Interoperability with IP network: Due to introduction of new ID handling functions, the ID/locator separation-based mobility management networks need additional proxy functions for interoperability with each other and with the traditional IP networks. For example, there are proxy functions being proposed for HIP, LISP, HIMALIS, and MOFI. The proxy functions can exist either in host or in gateway or both.

Besides providing better mobility management, ID/locator separation-based mobility architectures are also favorable in supporting heterogeneous types of network layer protocols, enhancing security, alleviating BGP routing overhead, and making architecture extendible. These issues have been researched and standardized in various standard development organizations (SDOs) such as IETF and ITU. Although we listed only IETF standards on ID/locator separation networking protocols in the previous sections, there are similar work in ITU (for detail, please see ITU-T Recommendations Y.2015, Y.2057, Y.3032, and Y.3034).

Definitions

Mobility in multicast means the technical ability to provide mobility support in IP multicast com-

munications. IP multicast session can be resumed after the change of point of attachment by a mobile terminal, without mobility management consideration. But the traditional IP multicasting has two technical issues in a mobility event; one is that the multicast session will be disrupted. Second, a join procedure for the multicast session takes a considerable time for the multicast membership update and multicast routing path update after the IP connection is established. To avoid such time-consuming procedure and session disruption by mobility in IP multicast communication, mobility support mechanisms for IP multicast are required. Depending on mobility management protocol such as Mobile IP or Proxy Mobile IPv6, or other mobility protocols over which IP multicast works, design criteria for mobility management extension are considered.

Historical Background

IP multicast is a well-known transmission technique that efficiently can deliver an IP packet from a sender to multiple receivers by duplicating the packet over IP multicast-enabled networks, without creation and management of multiple IP sessions per content request. Setting up a multicast session is powered by two main technologies: (i) multicast membership group management and (ii) multicast routing. A multicast group is a set of network devices identified by a common multicast address. For the receivers interested in receiving the IP packets of a certain multicast group, it is required to subscribe the membership group using Internet Group Management Protocol (IGMP) for IPv4 (Cain et al. 2002) or Multicast Listener Discovery (MLD) for IPv6 (Vida and Costa 2004). After the interested multicast group information is gathered by the local multicast router, it should send a join message with the multicast group information to the upstream multicast router for establishing a multicast branch between the two multicast routers on the requested multicast group, using multicast routing protocol such as PIM-SM and PIM-DM (Fenner et al. 2016; Adams et al. 2005) or IGMP/MLD Proxy (Fenner et al. 2006) (Fig. 1).

Mobility in Multicast,

Fig. 1 IP multicast transmission to multiple receivers

As wireless/mobile network is evolving and growing with the demand of IP multimedia service, mobility in multicast began to study in earnest with the advent of Mobile IP for the IP session continuity support of a mobile terminal. There are a variety of solutions for mobility in multicast, addressing and/or mitigating the tunnel convergence issue, join latency, point of failure, and so on. In Romdhani et al. (2004), IP multicast support mechanisms over mobile networks were comprehensively investigated, dealing with technical challenges and solutions for mobile source and mobile receiver over Mobile IP (MIP) and its variants such as Fast Mobile IPv6 (FMIPv6) and Hierarchical Mobile IPv6 (HMIPv6).

As Proxy Mobile IPv6 (PMIPv6) addressing the limitations of the host-based mobility protocols (i.e., Mobile IP) appeared (Gundavelli et al. 2008), the design approach for IP multicast support over PMIPv6 has been investigated in IETF Multicast Mobility (MULTIMOB) WG, with the aim of specifying IP multicast support and optimization solutions aligned with PMIPv6 networks (Schmidt et al. 2011; Zuniga et al. 2013) and handling the behavior of IGMPv3/MLD for wireless networks and mobility (Asaeda et al. 2012). All the produced RFCs in IETF MULTIMOB WG are as follows:

- RFC 6224: Base Deployment for Multicast Listener Support in Proxy Mobile IPv6 (PMIPv6) Domains
- RFC 6636: Tuning the Behavior of the Internet Group Management Protocol (IGMP) and

Multicast Listener Discovery (MLD) for Routers in Mobile and Wireless Networks

- RFC 7028: Multicast Mobility Routing Optimization for Proxy Mobile IPv6
- RFC 7261: Proxy Mobile IPv6 (PMIPv6) Multicast Handover Optimization by the Subscription Information Acquisition through the LMA (SIAL)
- RFC 7287: Mobile Multicast Sender Support in Proxy Mobile IPv6 (PMIPv6) Domains
- RFC 7411: Multicast Listener Extensions for Mobile IPv6 (MIPv6) and Proxy Mobile IPv6 (PMIPv6) Fast Handovers

For tackling the problems and limitations of the centralized mobility management, i.e., MIP and PMIPv6, Distributed Mobility Management (DMM) has appeared in IETF DMM WG, analyzing the issues of centralized mobility management and extracting the requirements (Chan et al. 2014). In the requirements, IP multicast issues and problems in the centralized mobility management are analyzed, and design considerations for IP multicast over DMM are given.

Key Points

For IP multicast deployment over the mobile networks, it is essentially required to install one of the two IP multicast agents or both into the mobility management entities. The one is an Internet Group Management Protocol (IGMP)/Multicast Listener Discovery (MLD) Forwarding Proxy (in short IGMP/MLD Proxy) (Fenner et al. 2006); the other is a

multicast routing protocol. Both or each of them can be used for providing multicast service over wireless/mobile networks. Though the mobile network can be deployed with both multicast membership protocol and multicast routing protocol, the multicast membership protocol can solely be used and installed in the mobility management entities, and the multicast traffic distribution in the core network can be implemented and deployed by an operator-specific solution. On the other hand, the multicast routing infrastructure can solely be used for multicast packet distribution over the multicast core network, while the subscription of a certain multicast group can be implemented by an operator-specific solution. The IGMP/MLD Proxy provides an available option to associate the mobile network with a multicast infrastructure. It is lightweight compared to the multicast routing protocol and does not require the multicast routing protocol support. Due to the reason, it has been tried to use IGMP/MLD Proxy in PMIPv6 networks (Schmidt et al. 2011; Zuniga et al. 2013). In any cases chosen from the deployment options, mobility management in multicast should consider the following design issues and KPIs.

- *Multicast Traffic Duplication:* IP multicast works per group, not per terminal, while IP mobility management is provided and handled per terminal with a tunneling method. IP multicast aims to provide an efficient transmission of the same packet for multiple terminals. Suppose that there are multiple terminals attached at the same mobility access router and they are supported by the IP tunnels from their home networks in an IP mobility architecture. IP multicast subscription on the same multicast channel for individual mobile terminal will be delivered through each tunnel and multicast traffic will be duplicate. This problem was described in PMIPv6-based networks with a proposed solution to tackle the problem in Jeon et al. (2009), which has been contributed for an optimized IP mobile multicast solution (Zuniga et al. 2013). This

problem has been identified in a distributed mobility environment, as analyzed in Jeon et al. (2012) (Fig. 2).

- *Join Latency:* To receive a copy of IP multicast packet, a receiver should join a group by initiating a multicast membership request when it learns of the group using the membership subscription protocol (IGMP or MLD). The IP multicast router sends a join message to the upstream multicast router to join the group requested from the receiver. Then, an IP multicast branch is established between the two multicast routers. This process takes a considerable time, so reducing the join latency is of importance for seamless service continuity in IP mobile multicast. For addressing the issue, tuning the behavior of IGMP and MLD protocols is required, since the behaviors and parameters of the protocols are originally specified for wired networks (Asaeda et al. 2012). Sending the IP multicast context information to a predicted mobility access router was suggested by extending mobility protocol (Jeon et al. 2009; Figueiredo et al. 2015) or using context transfer protocol (Von Hugo and Asaeda 2013).

Key Applications

- *Mobile IPTV:* Mobile IPTV is a popular application where mobility in multicast can be provided. Nowadays, for receiving multimedia streaming such as drama, movie, and news, IP multicast with mobility can be considered for watching streaming contents, particularly in commute time.
- *Personal Broadcasting Service (PBS):* personal broadcasting service where a mobile sender broadcasts the real-time streaming in a street or moving car is going to be popular. The multicast mobility architecture for PBS was designed and demonstrated in Medieval (2012).
- *Multimedia Broadcast/Multicast Service (MBMS):* MBMS is the 3GPP-based multicast/broadcast platform, which enables multicast/broadcast services for mobile

Mobility in Multicast,
Fig. 2 Multicast traffic
 duplication problem in a
 mobile IP-based network

terminals. MBMS aims for efficiency of multimedia traffic transmission on the same region covered by a base station (BS). However, due to the economies of channel popularity per BS region and dedicated MBMS radio frequency, it is somewhat deprecated.

Modeling Approaches for Simulating Molecular Communications

Molecular communication simulators; Simulation of diffusion-based molecular communications

Definition

Molecular communication involves biological entities that are able to transmit and receive molecules, which represent the information signal.

Historical Background

The molecular communications (MolCom) represent an emerging research area that consists of transmission of information by means of exchange of molecules, carried out by either natural or artificial nanomachines. The physical mechanisms that allow transferring information at such small scales are typically inspired by the biological mechanisms that exist in living

bodies to exchange many types of signaling molecules, such as proteins, pheromones, and immune system activation signals, both within and between different cells. The diffusion-based MolCom are the most studied mechanisms; they are based on the molecule propagation in the fluid medium according to the laws of diffusion (Philibert 2006), without the presence of any flow or drift.

In recent years, a multitude of significant breakthroughs occurred in some strategic socioeconomic fields (Akyildiz et al. 2008). They encompassed multidisciplinary research, bringing together information and communication technologies, molecular biology, physics, chemistry, biotechnology, environmental control, and material science. Together, they will allow realizing the vision of transferring information within biological environments at extremely small scales, down to a size comparable to that of molecules. In this case MolCom are considered an alternative approach to electromagnetic communications due to their unique features of biocompatibility and minimal invasiveness, which are essential for them to be used in living bodies.

Key Applications

Up to now, most interesting potential applications have been identified in the biomedical field (Felicetti et al. 2016). The emerging applications of MolCom techniques focus on both emulations and the development of body area nanonetworks oriented to the diagnosis and treatment of diseases.

As for the first one, the emulation of nanoscale biological processes allows achieving personalized predictions of the evolution of diseases, starting from a limited number of biomarkers, avoiding any traditional in vivo tests on patients (Hood et al. 2011; Bragazzi 2013) helping medical personnel to identify optimal treatments. The computational models are based on a detailed characterization of the molecular communication parameters done by using results of in vitro and in vivo experiments.

For the latter one, the design of nano-sensors/actuators could allow the detection and treatment of a large set of diseases (e.g., cardiovascular diseases, tumors, etc.). In fact, these nano-devices could activate the immune system and/or trigger drug delivery systems in small specific areas without affecting the rest of the body (i.e., smart drugs).

However, other fields, such as food production, functionalized materials and fabrics, as well as environmental and military applications, can be envisioned (Akyildiz et al. 2008).

Communication Models

The most simple and energy-efficient propagation model, without any external cause, is the diffusion-based molecular communication system. In the last years, several researches have been focused on the theoretical analysis and mathematical modeling of the propagation medium, on the receiver modeling (Yilmaz et al. 2014), and on the reception techniques.

In diffusion-based systems, the transmit signal is encoded on the physical characteristics of information molecules (e.g., cytokines, hormones, DNA). Those are able to randomly propagate in the fluid medium via diffusion spreading in the environment according to the negative gradient of the concentration with a velocity that depends on the thermal energy and on the particle size.

The information can be encoded on the concentration of emitted particles, on the frequency of emission, and on the type of released molecules.

The information molecules can interact with the receiver node in several ways, changing or not their concentration around the receiver. The simplest reception model assumes the ideal passive (or transparent) receiver which is permeable to the hitting molecules and is capable only to count the number of the molecules inside its volume. This means that the hitting molecules may unavoidably contribute to the received signal more than once in different symbol intervals

and the receiver may encounter high intersymbol interference (ISI) (Deng et al. 2017).

In a more realistic molecular communication system, each molecule is removed from the environment after the adsorption, and it contributes only once to the received signal. The adsorption takes place through the surface receptors that cover the external membrane of the receiver node. These receptors are able to react only with specific types of information molecules. In more detail, these receptors may adsorb or bind with these molecules. In the first case, the chemical complex formed by the molecule (known also as ligand) and the receptor is internalized by the nanomachine and follows a process known as trafficking (Lauffenburger and Linderman 1996). On the latter case, it may happen that some molecules desorb from their receptors and may contribute several times to the received signal.

In what follows, the main receiver models for a 3D diffusion-based molecular communication system in a fluid environment are analyzed, from the more complex and general to the simplest one. As already mentioned, in the most general case, the information molecules released from the transmitter can be adsorbed and desorb from the surface of the receiver, and the net number of adsorptions is counted for information decoding. This general model will be introduced first, and then the other models will be derived from it.

The overall system consists of a point transmitter and a spherical receiver in an unbounded homogeneous environment. The point transmitter is located at a distance r_0 from the center of the receiver and is at a distance $d = r_0 - r_r$ from the nearest point on the surface of the receiver with radius r_r . The surface of the receiver node is assumed to be covered by a number of compliant receptors that can adsorb at most one molecule at a time. It is assumed that the spherical receiver has no physical limitation on the number or placement of receptors on its surface. Thus, there is no limit on the number of molecules adsorbed to the receiver surface. This is an appropriate assumption for a sufficiently low number of adsorbed molecules, or for a sufficiently high concentration of receptors.

Emission Process

The point transmitter emits the information molecules at $t = 0$. Fick's diffusion equation describes the propagation of the information molecules in the environment:

$$C(r, t \rightarrow 0 | r_0) = \frac{1}{4\pi r_0^2} \delta(r - r_0), \quad (1)$$

where $C(r, t \rightarrow 0 | r_0)$ is the molecule distribution function at time $t \rightarrow 0$ and distance r from the center of the receiver with initial distance r_0 . The first boundary condition is:

$$\lim_{r \rightarrow \infty} C(r, t | r_0) = 0, \quad (2)$$

such that at arbitrary time, the molecule distribution function equals zero when r goes to infinity.

Propagation via Diffusion

The released information molecules randomly diffuse in the medium by means of Brownian motion (Berg 1993) colliding with other molecules. In the case in which the concentration of information molecules could be assumed to be sufficiently low, the collisions between information molecules could be ignored (Berg 1993). This means that each information molecule diffuses independently with constant diffusion coefficient D .

Fick's second law describes the propagation model in a 3D environment (Yilmaz et al. 2014; Philibert 2006):

$$\frac{\partial C(r, t | r_0)}{\partial t} = \nabla^2 (D \cdot C(r, t | r_0)) - k_d C(r, t | r_0). \quad (3)$$

In (3), we have also included the negative contribution of molecule degradation. In fact, signaling molecules released in the environment may degrade with a certain probability and transform into molecules not recognized by the receiver. k_d is the degradation reaction coefficient (time^{-1}), which is the time constant of this chemical phenomenon. In the following, we assume no molecule degradation, i.e. $k_d = 0$.

A more general case considers also the presence of a non-negligible flow in the environment, which often is also constrained in a limited space. This case, that will be not treated in this chapter for space limitation, is well modeled by the advection-diffusion equation (Gentile et al. 2008).

Reception

A generic receiver node should be capable of adsorbing incoming molecules that hit its surface or reflect them back into the fluid environment, based on the adsorption rate k_1 ($\text{length} \times \text{time}^{-1}$), which depends on the chemical affinity of each molecule with the surface receptors of the receiver node. The adsorbed molecules either desorb or remain stationary at the surface of the receiver, based on the desorption rate k_{-1} (time^{-1}).

The adsorption and desorption reactions that can occur on its surface give the second boundary condition of the information molecules:

$$D \frac{\partial (C(r, t | r_0))}{\partial r} \Big|_{r=r_r^+} = k_1 C(r_r, t | r_0) - k_{-1} C_a(t | r_0), \quad (4)$$

where $C_a(t | r_0)$ is the average concentration of molecules that are adsorbed to the receiver surface at time t . The change in the adsorbed concentration over time is equal to the flux of diffusion molecules toward the surface:

$$\frac{\partial C_a(t | r_0)}{\partial t} = D \frac{\partial (C(r, t | r_0))}{\partial r} \Big|_{r=r_r^+}. \quad (5)$$

Combining (4) and (5), the radiation boundary condition is obtained, and it shows that the equivalent adsorption rate is proportional to the surface molecule concentration:

$$\frac{\partial C_a(t | r_0)}{\partial t} = k_1 C(r_r, t | r_0) - k_{-1} C_a(t | r_0). \quad (6)$$

At $t = 0$, there are no information molecules at the receiver surface, so the second initial condition is:

$$\begin{aligned} C(r_r, 0|r_0) &= 0, \\ C_a(0|r_0) &= 0. \end{aligned} \quad (7)$$

Depending on the values assumed by both k_1 and k_{-1} , it is possible to define how the receiver node works, as defined below:

- Both k_1 and k_{-1} are non-zero finite constants: (4) is the boundary condition for the adsorption/desorption receiver. A complete transient and steady-state solution for this quite general case can be found in Deng et al. (2015). A variation of this model, taking into account also the receptor occupancy status, is illustrated in Pierobon and Akyildiz (2011).
- k_1 is a non-zero finite constant and $k_{-1} = 0$, and (4) is the boundary condition for the partial absorbing receiver (or receiver with finite receptors). The partially absorbing receiver with finite receptors fits with the realistic case in which the complex formed by the ligand and the receptor is internalized. Clearly, this may happen only when a molecule binds to one of the compliant surface receptors; otherwise it will be reflected away. A quite complete treatment of the solution of this specific case can be found in Akkaya et al. (2015) and references therein.
- $k_1 \rightarrow \infty$ and $k_{-1} = 0$: (4) is the boundary condition for the fully adsorbing receiver. In this configuration, each colliding molecule with the surface of the receiver will be adsorbed without any further desorption. This configuration models the case in which the surface of the receiver node is largely covered by receptors compliant with ligand molecules. A quite complete treatment of the solution of this model can be found in Yilmaz et al. (2014).
- Finally, a further popular model, which is slightly different from those presented above, is the transparent (or virtual) receiver. In this model, a receiver is able to simply count the molecules crossing its volume, *without any interaction* with them (i.e., adsorption, desorption, or even bounces). Clearly, in this case the coefficients k_1 and k_{-1} are not used, and the

only boundary condition is (2). For this type of receiver, an interesting analysis is presented in Llatser et al. (2013).

The probability of finding a molecule at distance r and time t is given by the time-varying spherically symmetric spatial distribution $C(r, t|r_0)$. The cumulative fraction of adsorbed molecules at time t can be expressed as:

$$F(\Omega_{r_r}, t|r_0) = \int_0^t 4\pi r_r^2 D \frac{\partial C(r, \tau|r_0)}{\partial r} \Big|_{r=r_r} d\tau \quad (8)$$

where Ω_{r_r} represents the surface of the spherical receiver with radius r_r . Upon an emission of Q molecules at time $t_0 = 0$, the average number of adsorbed molecules after t seconds will be $N(\Omega_{r_r}, t|r_0) = QF(\Omega_{r_r}, t|r_0)$. The asymptotic concentration of adsorbed molecules can be found as $t \rightarrow \infty$ for the different formulations of $N(\Omega_{r_r}, t|r_0)$, depending on the values of k_1 and k_{-1} . As for the transparent receiver, the solution is simpler, and the average number of “counted” molecules is given by $N(\Omega_{r_r}, t|r_0) = C(0, t|r_0) V_r$, where V_r is the volume of the spherical transparent receiver.

For a treatment more focused on the chemical species involved into the adsorption and desorption reaction, that is the molecules or ligands, the receptors, and the complex obtained by their binding, the interested reader can refer to Lauffenburger and Linderman (1996).

Mapping Models on Simulation Platforms

BiNS Biological and Nanoscale Communication Simulator

General description BiNS is a simulation package for MolCom systems developed at the University of Perugia (Felicetti et al. 2012).

Its customizable design provides a set of tools which allow creating objects modeling the behavior of biological entities. They can be regarded as either nodes (transmitters, receivers), carriers, or

surrounding objects (e.g., vessel walls). In addition, BiNS permits to configure the properties of the simulated communication channel (e.g., the blood stream or the environment of an in vitro experiment) with the desired accuracy.

The simulator has been implemented in Java and contains generic type of software object, named Nano Object. Nodes and carriers are specific implementations of the Nano Object, and, although they share its general features, they can exhibit very different functions.

The simulation is organized in discrete time steps. Each step consists of a number of phases, in which software objects are triggered in order to execute the operations associated with their specific behavior. The main phases are:

- transmission phase
- reception phase
- information processing phase,
- motion phase
- object destruction phase (during which objects are removed due to lifetime expiration or because they exited from the area of interest)
- collision management phase, which implements the elementary interaction between particles.

BiNS has been validated through wet-lab experiments related to cardiovascular medicine.

Technical requirements and scalability The list of simulated nano-objects is split into smaller lists, which can be handled in parallel by a thread pool.

The simulator uses a fine-grained approach for handling collisions between objects. A collision can produce either a bounce or an assimilation. The latter happens only when a carrier collides with a compliant receptor on the surface of a node. The receptors can implement a non-negligible absorption time; thus a compliant particle could find a receptor in either busy or free state. The simulated environment can be either unbounded or bounded by a surface of custom shape, referred to as simulation domain. For example, in order to simulate communica-

tions within a blood vessel, a cylindrical volume was used. Within a domain, the octree paradigm allows distributing the workload associated with the management of the objects in the domain volume to different threads. There is an ongoing effort for the GPU porting of the collision handling algorithm in order to reduce the computational time significantly.

N3Sim

General description N3Sim (Llatser et al. 2011) is a Java-based complete simulation framework for diffusion-based molecular communications, which allows the evaluation of the communication performance of molecular networks with several transmitters and receivers in an infinite space with a given concentration of molecules. The transmitters encode the information by releasing particles into the medium, thus varying the concentration rate in their vicinity. The diffusion of particles through the medium is modeled as Brownian motion, taking into account particle inertia and collisions among particles. Finally, the receivers decode the information by sensing the local concentration in their neighborhood. It implements a three-layer architecture. The user interface layer interacts with the user to read the input data for the simulation, while the data layer writes the simulation results to files. The domain layer contains the intelligence of the system, i.e., the molecular communication model. N3Sim allows automating the execution of multiple simulations in a simple manner by means of user-defined scripts.

Technical requirements and scalability N3Sim is designed to be executed on a single machine with Java 1.6 or higher. The simulator has been tested both on Linux and Windows. The scalability of the simulator can be improved by selecting a larger value of the simulation time step (at the expense of the accuracy) or by deactivating the collisions among molecules in scenarios with a low molecular concentration. As an example, simulations with up to 10^6 simultaneously emitted molecules have been

successfully performed. The time granularity of a simulation is defined by the user by choosing the simulation time step in the configuration file (typically a few *ms*). The simulation space can be either bounded or unbounded, and both two-dimensional and three-dimensional configurations are supported.

NS-3 Based Simulators

General description NS-3 is a discrete-event network simulator for Internet systems, which was not originally developed for MolCom simulators. Nevertheless, its flexible structure has allowed implementing some basic elements of MolCom. In particular there are two simulation tools that have been developed in NS-3: one in the framework of the IEEE P1906.1 working group (Bush et al. 2015; IEEE Std 1906.1-2015 2016) and another specific implementation for bacteria communications (Jian et al. 2017).

NS-3 is organized in different software libraries that can work together. User programs, written in C++ or Python programming languages, can adapt these libraries or be linked with them. External animators and data analysis and visualization tools are available. Nevertheless, in order to exploit the full potentials of the NS-3, the command line interface is suggested.

Technical requirements and scalability The simulator is designed to be executed on a single machine. The minimal requirements to execute basic simulations are a gcc or clang compiler and Python interpreter. The simulation granularity is defined by users. Event design can be adapted to any granularity and is synchronized in the simulator implementation processing loop.

AcCoRD

General description The Actor-based Communication via Reaction-Diffusion (AcCoRD) is an open-source generic reaction-diffusion MolCom simulator developed in C language (Noel et al. 2017). The actors can be both transmitter and receivers, and the simulation environment is defined as a collection of microscopic and

mesoscopic regions that differ for the simulation accuracy and the computational cost. In the microscopic region, each molecule is individually modeled in each time step, whereas in the mesoscopic one, the total amount of molecules in each region is analyzed. Chemical reactions (e.g., molecule degradation, reversible/irreversible surface binding, etc.) can be defined in the propagation environment.

Technical requirements and scalability

Microscopic and mesoscopic regions can be combined and dimensioned according to the simulation needs, balancing the local accuracy with the computational cost. Also a visualization tool developed in MATLAB is included in the simulator allowing an offline visualization of the simulated environment.

Simulators for Specific MolCom Environments

In addition to the general simulation platforms presented in the section before, there are a number of more specific simulation packages targeted to specific environments. Examples of these simulators include platforms dealing with bacteria colonies (Jian et al. 2017; Wei et al. 2013) introduced also in section “NS-3 Based Simulators”, calcium signaling (Barros et al. 2015), or nervous systems (Malak et al. 2014).

MolCom Simulators Functional Comparison

A comparison of the main simulators that have been developed to characterize the broad set of MolCom systems is sketched in Table 1, where the compatibility with the different receiver models introduced above is illustrated.

However, this is a rough classification of the available simulation tools. In fact, more realistic and refined models can be simulated only by a subset of these ones. For instance, when the interactions between molecules are significant, diffusion equations may become nonlinear (Aranovich and Donohue 2005), regardless of the receiver model. Also, the partial adsorbing receiver can be modeled with a finite adsorption time for each receptor, which is more realistic.

Modeling Approaches for Simulating Molecular Communications, Table 1 Compatibility of the most popular MolCom simulators with the reception models

Simulator	Adsorption/desorption receiver	Partial adsorbing receiver	Full adsorbing receiver	Transparent receiver
BiNS ^a	Easy to upgrade ^c	Yes	Yes	Yes
N3Sim ^b	No	No	Yes	Yes
NS-3 ^c	No	No	No	Yes
AcCoRD ^d	Yes	Yes	Yes	Yes

^a Available on <http://conan.diei.unipg.it/lab/index.php/product/biological-nanoscale-simulator-bins2>

^b Available on <http://www.n3cat.upc.edu/tools/n3sim/download>

^c Available on <https://www.nsnam.org/releases/>

^d Available on <https://warwick.ac.uk/fac/sci/eng/staff/ajgn/software/accord/downloads/>

^e A minor upgrade is necessary to implement desorption by applying the Algorithm 1 illustrated in Deng et al. (2015)

These more complex but also realistic systems can be simulated by BiNS2. At the same time, the desorption functionality is already implemented in AcCoRD, whereas BiNS2 needs an upgrade to implement it.

Definitions

Molecular signaling is a way of communicating via use of molecules. There are still many applications and environments where the classical technologies are not convenient or appropriate. Inspired by nature, one possible solution to these problems is to use chemical signals as carriers of information, which is called molecular communication (MC). Modulation in *synthetic* MC is the way of embedding the information on one or more properties of molecule emission process.

Historical Background

In 1959, Richard Feynman gave a lecture at American Physical Society meeting in Caltech that is titled “There is Plenty of Room at the Bottom” (Feynman 1959). The talk was pointing out the manipulation and controlling things at a small scale with a huge potential to advance the knowledge frontier. Over the past couple of decades there have been considerable advancements in the fields of nanotechnology, biotechnology, and microrobotics, where designing and engineering of microscale or nanoscale devices begin to take shape. On the other hand, the cooperation and coordination of these tiny devices necessitates the miniaturization of communication networks, in which one of the techniques is MC.

Molecular signaling/communication is at its infancy phase having been first proposed in 2005 from an engineered communication perspective (Nakano et al. 2005). Many theoretical and simulation-based studies are published in the molecular communications (MC) domain. In this entry, the works related to MC modulation techniques are given in chronological order and from simple to complex systems. Readers may feel the chronological order while reading the entry.

Background on Molecular Communication

In MC, molecules are utilized to convey information among communication nodes at micro-

and macroscales (Farsad et al. 2016b). Some of the microscale MC systems can be listed as quorum sensing in bacteria (Cobo and Akyildiz 2010; Abadal and Akyildiz 2011), neurotransmitter signaling in neuromuscular junctions (Kuran et al. 2013), and inter-cell calcium signaling (Nakano et al. 2005; Kuran et al. 2012). Examples of macroscale MC systems in nature include pheromone signaling among plants, chemical signaling among animals, and odor tracking of blue crabs in the ocean (Zimmer and Butman 2000).

In MC, information molecules propagate in a fluid environment via various processes (such as diffusion), and they arrive at the receiver node in a probabilistic manner in which the received molecules constitute the received molecular signal (Farsad et al. 2016b). In its basic form, an MC system mainly consists of a transmitter node, fluid environment, information molecules, and a receiver node (Nakano et al. 2013; Farsad et al. 2016b). In the following subsections, first the common performance metrics for MC channels are given followed by the types and dynamics of the modulation techniques.

Common Metrics for Molecular Communication

One of the first metrics to evaluate the modulation techniques that have been used in MC literature is the system response. This metric mainly focuses on the number of received molecules with respect to time. It is generally used to show the effects of different channel types (e.g., free diffusion, vessel-like environment, constrained diffusion) and transmitted molecular signal waveforms (e.g., sinusoidal, square) on the received signal.

Other common metrics can be listed as bit error rate (BER), symbol error rate (SER), and the channel capacity. In the MC literature, as a performance metric, BER or SER is usually evaluated against several system parameters such as signal-to-noise ratio (SNR), transmitted power, symbol duration, communication distance, and diffusion coefficient. As for SNR, the key chal-

lenge is to clearly define what is the definition of noise in this domain and which noise sources to consider (Nakano et al. 2013). Channel capacity metric is evaluated based on the given error rates and the channel model and provides the achievable data rate of the communication system in question. A key point regarding the correctness of this metric is the selection of the appropriate channel model. Currently, most of the MC literature assume a memoryless MC channel to evaluate the channel capacity. However, as described by Genc et al., due to the diffusion-based dynamics of the MC channel, the memoryless assumption is far from appropriate in the MC domain, and instead a model with memory is required (Genc et al. 2016).

After briefly mentioning these common performance metrics, the rest of the entry will be focused on the types of modulation techniques used in MC systems. At the end of this entry, a table of studies are given in a table with also mentioning the metrics used in each study.

Modulation Techniques

All MC modulation techniques depend on releasing special molecules called messenger molecules (MM) from the transmitter and modulating the bit values of a given message upon the features of these MMs. There are works in the MC literature on the selection of feature(s) to be used to represent the information. These works can be broadly classified into four groups:

Concentration-based Techniques Information is embedded upon the varying concentration level of the transmitted signal.

Type-based Techniques Information is embedded upon the type of the MMs of the transmitted signal.

Timing-based Techniques Information is embedded upon the MM release time instances.

Hybrid Techniques Techniques utilizing more than one of the three features (concentration,

type, timing) of the transmitted signal to represent information.

Concentration-Based Techniques

The main idea of concentration-based techniques is carrying information on varying released MM concentration over fixed period discrete time slots (i.e., symbol durations, t_s). In its simplest form, each symbol represents one bit value and is called on-off keying (OOK). In OOK, the transmitter releases a fixed number of MMs (i.e., n_1) if the corresponding bit value (k -th symbol $S[k]$) is bit-1 or releases no molecules at all if it is bit-0 Mahfuz et al. (2010). At the receiver side, the receiver counts the number of MMs arrive within each symbol duration (i.e., $N^{Rx}[k]$) and makes a threshold-based decision to decode the bit value of the given symbol duration ($\hat{S}[k]$).

A more generalized version of OOK is called concentration shift keying (CSK) where each symbol, depending on the system design, represents m -bits of information (Kuran et al. 2011). From a communication point of view, CSK is akin to amplitude modulation (AM) method in analog modulation and amplitude shift keying (ASK) in digital modulation. In CSK, for the k th symbol in the message, the transmitter releases $N^{Tx}[k]$ number of MMs depending on the current symbol value as

$$N^{Tx}[k] = n_{S[k]}, \quad S[k] \in (0, 1, \dots, 2^m - 1), \quad (1)$$

where $S[k]$ can take one of the 2^m symbol values (e.g., $\text{sym}_0, \text{sym}_1$) in the modulation alphabet and $n_{S[k]}$ denotes the number of molecules to emit for the symbol $S[k]$. In order to decode $\hat{S}[k]$ from the received signal, the receiver uses $2^m - 1$ thresholds (i.e., $\lambda_0, \lambda_1, \dots, \lambda_{2^m-2}$) as

$$\hat{S}[k] = \begin{cases} \text{sym}_0, & N^{Rx}[k] < \lambda_0 \\ \text{sym}_i, & \lambda_i \leq N^{Rx}[k] < \lambda_{i+1} \\ \text{sym}_{2^m-1}, & \lambda_{2^m-2} \leq N^{Rx}[k] \end{cases} \quad (2)$$

Type-Based Techniques

A second group of modulation techniques, called type-based techniques, focuses on using multiple types of MMs in the communication system as a basis of a modulation technique. In these techniques, the transmitter has the capability of releasing different types of MMs (mm_{type}) that can only be received by a particular type of receptors at the receiver surface.

In the first type-based modulation technique, molecular shift keying (MoSK), each different symbol value (sym_i) is represented by a specific type of MM (Kuran et al. 2011; Aminian et al. 2015; Galmés and Atakan 2016). During each symbol duration, the receiver counts the number of arriving MMs for each MM type and decodes $\hat{S}[k]$ based on thresholding or the majority decision:

$$\hat{S}[k] = \text{sym}_i, \quad \text{where } i = \arg \max_r N_{mm_r}^{Rx}[k]. \quad (3)$$

Compared to CSK, MoSK considerably reduces the intersymbol interference (ISI) element of the signal due to the fact that each bit value is represented by a different type of molecule. On the other hand, it increases the system complexity since the transmitter is required to synthesize different types of molecules and the receiver is required to have multiple receptors on its surface. Moreover, molecule types should be similar in terms of diffusion coefficient due to propagation dynamics and single symbol duration.

Timing-Based Techniques

The main idea of timing-based modulations is to encode the information on the release time of the information molecules. In its simplest form, emission of MMs is done at an instance in the symbol slot where the time instance can be between the start and the end of the symbol slot. The time instance represents the intended symbol, and the receiver aims to detect the emission time hence the intended symbol. Capacity limit of timing-based techniques is derived and analyzed in Farsad et al. (2016a) and Murin et al. (2016).

Modulation in Molecular Signaling, Fig. 1 Example scenario showing the emission times with the bit sequence 011

Timing-based approach is also called pulse position modulation (PPM), which is similar to PPM in optical communications (Garraalda et al. 2011). In the binary case of timing-based techniques, the transmitter simply emits molecules at t_{sym_0} for sym_0 (which is usually at the start of the symbol duration) and emits molecules at t_{sym_1} for sym_1 (which is usually around the mid symbol duration) (Fig. 1).

Another release timing-based modulation scheme is called time-elapse communication (TEC) and is proposed for slow networks such as on-chip bacterial communication (Krishnaswamy et al. 2013). In TEC, information is encoded in the time interval between two consecutive pulses (i.e., two consecutive pulses of information particle transmission), which is similar to pulse-width modulation (PWM). At the receiver side, the information is decoded by measuring the duration between two pulses. The authors showed that TEC can outperform on-off keying when techniques such as differential coding are used.

Hybrid Techniques

The three modulation techniques addressed above constitute the main categories of modulation techniques for MC. These techniques, which utilize the molecular concentration, type, or release timing, are simple and easy to implement. They show low system complexity unless the modulation order goes up to very high levels. However, in practice more efficient ways to enhance performance depending on the system conditions are required. This subsection introduces more advanced techniques most of which are operated by combining two or more basic principles.

In a molecular concentration-based modulation system, one of the main issues to be solved is ISI. Since the same type of MM is used over multiple symbol duration, previously transmitted molecules affect the current symbol, which act as interference. Thus, there have been many studies aiming at effectively eliminating the ISI. The following techniques merge the advantages of CSK and MoSK: molecular concentration shift keying (MCSK) (Arjmandi et al. 2013), molecular transition shift keying (MTSK) (Tepekule et al. 2014), and zebra-CSK (Pudasaini et al. 2014).

Arjmandi et al. proposed a hybrid technique called MCSK, where if $S[k] = \text{sym}_1$, the transmitter releases (mm_a) type of MMs if it is an odd-numbered symbol or releases (mm_b) type of MMs if it is an even-numbered symbol Arjmandi et al. (2013). Similar to binary CSK, in case $S[k] = \text{sym}_0$, the transmitter does not release any MMs. The receiver decodes the signal by checking the concentration of (mm_a) or (mm_b) depending on the symbol parity. In the binary case, MCSK outperforms MoSK in terms of BER due to the fact that the ISI component of the molecular signal after a sequence of sym_1 's grows too large so that it is highly likely that the next symbol with sym_0 will be mis-decoded as sym_1 . The alternating approach of MCSK remedies such mis-decodings. However, the advantage of MCSK diminishes in the quadruple case consequently, quadruple MoSK outperforms quadruple MCSK.

Tepekule et al. proposed a hybrid technique called MTSK to eliminate the destructive ISI while utilizing the constructive ISI (Tepekule et al. 2014). The MTSK is also similar to MCSK, but it determines the molecule type to be transmitted considering the current and the previous symbols. MTSK changes the molecule type at the symbol transitions, which results in reduction of the destructive ISI.

A short comparison of all the modulation techniques mentioned in this entry is given in the following table based on their modulation technique group, receiver type, environment considered, and the performance metric used in the evaluation of the described technique

Modulation in Molecular Signaling, Table 1 Comparison of modulation techniques for molecular communication

Technique name	References	Group	Receiver type	Metrics used
CSK	Kuran et al. (2010, 2011), Mahfuz et al. (2011), and Lin et al. (2012)	Concentration	Abso-FPP	System Resp., Ch. capacity, SER
MoSK	Kuran et al. (2011), Aminian et al. (2015), and Galmés and Atakan (2016)	Type	Abso-FPP	Ch. capacity
Timing	Farsad et al. (2016a) and Murin et al. (2016)	Timing	Abso-FPP	Ch. capacity, BER
PPM	Garraalda et al. (2011)	Timing	Passive	System Resp.
TEC	Krishnaswamy et al. (2013)	Timing	Microfluidic	Ch. capacity
MCSK	Arjmandi et al. (2013)	Hybrid	Abso-FPP	BER
MTSK	Tepekule et al. (2014)	Hybrid	Abso-FPP	BER
Zebra-CSK	Pudasaini et al. (2014)	Hybrid	Abso-FPP	Ch. capacity

(Table 1). As for the receiver types, Abso-FPP refers to an absorbing receiver design which considers the first passage probability (FPP) of the MMs, whereas passive refers to a passive receiver in which upon coming into contact with the receiver, the MMs are not absorbed but are still allowed to move around in the environment.

Key Applications

The potential applications of MC include medical applications, control of chemical reactions, coordination among nanorobots in microscales, underground communications, underwater localization and communications, environmental monitoring, communication applications in pipes or duct systems, and coordination among search and rescue robots for harsh environments in macroscales.

Definition

Molecular bit detection is the process at a molecular communications (MC) receiver of distinguishing between ones and zeros that have been sent by a transmitter.

Historical Background

Although Harry Nyquist is most often remembered for establishing 2 W pulses per second as the maximum signaling rate that can be supported over a baseband channel of bandwidth W, he also provided the axioms on which digital communications are built (Nyquist 1928). These are the division of time into defined intervals that are now referred to as symbol intervals and the conveying of information by changing a signal property in these intervals. The use of one bit of information per symbol leads to one binary digit (bit) being conveyed by each interval and to a bit rate that is purely the number of intervals per second. The binary digits must be put into a form that is matched to the transmission capabilities of the channel to be used. For most communication systems currently deployed, this entails modulating electromagnetic (EM) signals with the data to be transmitted leading to tractable analysis based on Maxwell's equations. Moreover, many established wired and wireless communication systems experience noise from thermal effects or other users that may be modeled using a Gaussian probability density function (PDF). This noise can cause problems in distinguishing a one bit from a zero bit causing bit errors. MC systems differ significantly from traditional communication systems in that they do not employ EM waves but rely on chemical carriers to convey their information. The natural world makes use of chemical signals for short- and long-range communications (Farsad et al. 2016). The biocompatibility and low energy nature of MC signals make them suitable for applications where EM signals cannot be employed. In general, MC may utilize molecular rails using carrier substances, may employ fluid flow, or may be based on diffusion (Deng et al. 2015). Here, the focus is on MC via Diffusion (MCvD) where molecules propagate randomly, making the process different to the spreading of EM waves. Despite the long evolutionary history of MCvD, it was only recently considered for microscale (Hiyama et al. 2005) and macroscale (Farsad et al. 2013) communication systems.

Foundations

The reliable recovery of data transmitted over a communication channel depends critically on the detection algorithm employed at the receiver. This estimates the signal from the noisy, distorted version that arrives after traversing a communication channel. In the case of bit detection, this will customarily entail the identification of a received bit as a "one" or a "zero." The most fundamental modulation scheme is referred to as on-off keying or OOK, where the presence of a signal in a bit period represents a "one" and signal absence a "zero." In the analysis that follows, this scheme is assumed for simplicity to illustrate the principle of bit detection. More sophisticated schemes have been developed for MCvD (Wang et al. 2017), and the analysis given below may be adapted accordingly. To achieve the goal of a communication system and transfer information from one location to another, a suitable signal must first be generated by the transmitter. This must then propagate to the receiver to be decoded. Thus, the system comprises transmitter, receiver, and channel. Here, the second two of these are particularly relevant since the receiver must make a decision on the received bits after they have suffered potential distortion and noise from the channel, which is the environment in which the signal propagates. In traditional communication systems, the channel is typically a wired or wireless connection carrying appropriate EM waves. In MCvD, particles act as chemical carriers to convey the information. These carriers are small, nanometers to micrometers in size, and travel in an aqueous or gaseous environment where they are free to move and diffuse. Noise may be introduced mainly by the channel through the diffusive nature of the carriers and the presence of other transmitters.

The received signal in MCvD is thus extremely random, and it is common to take the distribution of the received signal for a single molecule as the mean channel impulse response $\bar{h}(t)$. The number of molecules successfully received during the current bit interval or timeslot, N_0 , thus has mean given by:

$$\overline{N_0} = N_{tx} \overline{h}(t) \quad (1)$$

when the transmitter releases N_{tx} molecules to represent a one. There are several receiver models that have been proposed for different MCvD scenarios and each of these produces a different $\overline{h}(t)$. The principal categories are passive (Mahfuz et al. 2014), fully absorbing (Yilmaz et al. 2014), and reactive (Ahmadzadeh et al. 2016) depending of the behavior of the molecules and the receiver. The simplest form of $\overline{h}(t)$ results from a full absorbing receiver so that will be used as the basis for illustration here. The others produce results with similar behaviors but different optimum values and performance details.

Although diffusion is a well-established topic in Physics, the solution of its defining equation in realistic scenarios for communicating information is very challenging. Therefore, it is common to make the approximation illustrated in Fig. 1 to the scenario where a point source transmitter of molecules (TX) releases N_{tx} of these at time zero and they travel to the receiver (RX) via 3D Brownian motion. A fraction of the molecules arrives at RX within the timeslot.

As introduced above, the simplest case (assumed here) is that RX is fully absorbing, and molecules are captured as soon as they collide with the surface of RX. The major impact of the different receiver types is to alter the probability $P_{ca}(d, t)$ that RX captures a molecule at a time t and distance d as defined in Fig. 1.

For full absorption and a counting receiver, the capture probability may be written as (Yilmaz et al. 2014):

$$P_{ca}(d, t) = \frac{R}{d} \operatorname{erfc} \left(\frac{d - R}{\sqrt{4Dt}} \right) \quad (2)$$

where R is the receiver radius and D is the diffusion coefficient in the medium in which communication is taking place. The fundamental representation of information is via a binary form with the transmitted information represented by a sequence of binary symbols. Each consecutive time slot contains either N_{tx} or no molecules. Each timeslot is of duration t_s and molecules arriving at RX are captured and removed from the environment. RX can either measure the number of molecules arriving at a certain time instant (amplitude detection) or the accumulated total of molecules arriving during a certain time period (energy detection) (Llatser et al. 2013). The latter is a better choice, particularly for long distance transmission, since it requires far fewer molecules to be transmitted for the same bit error rate (BER) (Aijaz and Aghvami 2015). Thus, it is assumed that RX determines whether a one or a zero was sent by counting the number of absorbed molecules. There have been developments in recent years to add further sophistication to the detection process within the constraints of the capabilities of nano-machines. These have included the detection of sequences of bits using both the maximum a posteriori (MAP) and maximum likelihood (ML) criteria (Kilinc and Akan

Molecular Bit Detection, Fig. 1 Molecular communication channel

2013; Meng et al. 2014). ML produces optimum receiver performance and offers viable suboptimum methods for nano-machines in a range of scenarios (Noel et al. 2014; Fang et al. 2018; Kuscü and Akan 2018).

To avoid detailed discussion of the ML method, for which readers are referred to the references above, single bit threshold detection is assumed. Thus, if the number of molecules received in an intended time slot exceeds a pre-designed threshold, the symbol is interpreted as “one,” otherwise, it is interpreted as “zero” (Kuran et al. 2011). It is possible to develop an adaptive threshold (Damrath and Hoehner 2016), but again for simplicity a fixed value is assumed here. The approximation is made that molecules are released as an impulse at the beginning of the timeslot and diffuse toward RX to be either registered or not registered by RX within the timeslot. Thus, the distribution is derived from a series of trials with the outcome received or not received producing a binomial distribution for N_0 :

$$N_0 \sim \text{Binom}(N_{\text{tx}}, P_{\text{ca},0}) \quad (3)$$

where $P_{\text{ca},0} = P_{\text{ca}}(d, t_s)$. For large numbers of molecules, this may be conveniently approximated by a normal distribution

$$N_{0_Norm} \sim \mathcal{N}(N_{\text{tx}} P_{\text{ca},0}, N_{\text{tx}} P_{\text{ca},0} \{1 - P_{\text{ca},0}\}) \quad (4)$$

but this can be inaccurate when the number of molecules is small (Lu et al. 2015, 2016), leading to an asymmetric binomial distribution. Thus, for N_{tx} values in the hundreds of molecules, the Poisson approximation may be utilized:

$$N_{0_Pois} \sim \text{Pois}(N_{\text{tx}} P_{\text{ca},0}). \quad (5)$$

However, the molecules released at TX are not guaranteed to reach RX in one timeslot, so the remaining molecules may arrive later causing intersymbol interference (ISI). The number of molecules received from the previous i^{th} symbol in the current time slot is represented by N_i , $i \in \{1, \dots, I\}$, where I is the ISI length (Lu et al.

2015).

$$N_i \sim \text{Binom}(N_{\text{tx}}, P_{\text{ca},i} - P_{\text{ca},i-1}) \quad (6)$$

$$P_{\text{ca},i} = P_{\text{ca}}(d, \{i+1\} t_s). \quad (7)$$

With corresponding approximations

$$N_{i_norm} \sim \mathcal{N}(N_{\text{tx}} \Delta P_i, N_{\text{tx}} \Delta P_i \{1 - \Delta P_i\}) \quad (8)$$

and

$$N_{i_Pois} \sim \text{Pois}(N_{\text{tx}} \Delta P_i) \quad (9)$$

where $\Delta P_i = P_{\text{ca},i} - P_{\text{ca},i-1}$.

From these expressions, as shown in (Lu et al. 2017), it is possible to write down the effect of the number of previous slots that comprise the ISI length. Based on this analysis, a prediction of the MCvD system BER may be made by determining the probabilities that the noise sources will cause the signal at RX to be the wrong side of the decision level. Thus, in Fig. 2 the solid line indicates the BER obtained when the distance d is 7 μm and the diffusion coefficient D is 79.4 $\mu\text{m}^2\text{s}^{-1}$ (Lu et al. 2016).

In common with many other wireless systems, MCvD is also susceptible to one further source of error, namely interference from other users. This may be quantified by including an interfering receiver in the system that may absorb molecules destined for RX considered above (Lu et al. 2016). To illustrate a particularly problematic case, the dashed line in Fig. 2 illustrates the BER obtained over the original path when there is an interferer on the same side as the RX but at a distance of just 2 μm from TX (Lu et al. 2016). Although this is a particularly bad case that produces a power penalty of almost 7 dB at a BER level of 10^{-6} , it does graphically make the point that care must be taken when transmission is over more than just a point to point link. The use of different molecules for transmission to different receivers is possible (Kuran et al. 2011) but adds considerable complexity to MCvD systems.

Molecular Bit Detection,

Fig. 2 BER results for a MC system with 7 μm between TX and RX; solid line with no interferer; dotted line with an interferer 2 μm from TX

Improving Decisions

The reliability of information transmission can be increased by the employment of error correcting codes (ECCs) as is the case to improve the BER performance of conventional communication systems (Costello and Forney 2007). The small size and limited capabilities of nano-machines means that codes must be chosen for energy efficiency (Bai et al. 2014) and simplicity of implementation (Leeson and Higgins 2012). In recent years, considerable research efforts have been made in the development of nanoscale logic gates (Pilarczyk et al. 2018), making ECC implementation conceivable in the near future. ECC performance has thus been investigated numerically for MCvD in anticipation of future developments (Lu et al. 2015).

Key Applications

In areas where EM communication is not suitable, MC offers a solution for the near future. At the macroscale, this includes tunnel or pipe networks where experimental results have shown that EM waves fail to propagate but molecules get through but with a long delay (Qiu et al. 2014). This would facilitate, for example, the recovery of data

from embedded sensors or communications between search-and-rescue robots. Applications at the micro- or even nanoscale have driven the applications agenda to date with the promise of nanorobot drug delivery and tissue engineering (Nakano et al. 2013). In this regime, EM communication is difficult given the necessary ratio of the antenna size to wavelength ratio and the need for a line of sight using optical communications (Akyildiz et al. 2008).

Acronyms

BAN	Body Area Network
BANN	Body Area Nanonetwork
BAN ²	Body Area Nanonetwork
MC	Molecular Communication
IoNT	Internet of Nano Things
WBAN	Wireless Body Area Network

Definition

A wireless body area network (i.e., WBAN) generally consists of a central hub (i.e., base station) and a number of lightweight, low-powered, miniature, wearable sensors that operate in the proximity of a human body. Typically, it is located on the body, garment, underneath the skin, or deep into the tissue (Cavallari et al. 2014; Anjum and Wang 2016). WBAN is also known as a wireless body sensor network (WSN) or simply a body area network (BAN). On the contrary, a molecular communication (i.e., MC) system is an in-body BAN which consists of bio-nanomechanics such as biosensors and bio-actuators where the data transmission between the transmitter and receiver nanomachines is carried on by the encoded molecules (Cavallari et al. 2014; Nakano et al. 2012; Akyildiz et al. 2008). MC for WBAN is also termed as body area nanonetworks, i.e., BANN or BAN² (Suzuki et al. 2014; Atakan et al. 2012). The integration of MC-based in-body BANN and wearable WBAN is known as the Internet of Nano Things (IoNT) Dressler et al. (2015).

Historical Background

The use of the term “molecular communication” can be traced back to the 1970s where a number of researchers individually studied the various modes of molecular transmission among neuron cells (Dismukes and Key 1979). Later on, MC in host-parasite interaction and MC between plant-pathogen interaction are studied in Dixon and Lamb (1990) and Hadwiger et al. (1981), respectively. However, in the field of communication engineering, the concept of MC was developed in the early 2000s to create a communication network for bio-nanomachines (Nakano et al. 2005, 2012).

System Architecture

The system architecture of a MC typically consists of four key components – the sender, receiver, information bearing molecules (also known as signaling molecule), and propagation medium. To support the movement of the information molecule (i.e., IM), a MC may include an interface, transport, guide, and addressing molecules. All of these components are various forms of bio-nanomachines which are biochemically reactive, micrometer to nanometer range devices. The transfer of information in a typical MC takes the following five steps: encoding, transmitting, propagation, receiving, and decoding.

- *Encoding and Transmitting:* The encoding and transmitting of IM are done by the transmitter bio-nanomachine which is also known as the sender. The sender encodes the information in various forms within the molecules, such as the type of molecule used, their 3D structure (e.g., protein structure), sequential structure (e.g., DNA sequence), concentration (e.g., calcium concentration), number of molecule, release time of molecules, etc. The release of IM into the propagation medium is done

by budding vesicles (if the sender is a cell), opening the molecular gate (e.g., ion channel) of the sender membrane, or catalyzing a chemical reaction (Nakano et al. 2013).

- *Propagation:* The scales of propagation of the CM are divided in three categories – intracellular ($\leq 100 \mu\text{m}$), intercellular ($\leq 100 \mu\text{m}$), and inter-organ (up to few meters). The mode of propagation can be two types – passive and active. In the passive mode, a large number of molecules diffuse in all available directions. This is a slower process and does not require any infrastructure hence suitable for intracellular and intercellular communication. In addition, the propagation time t over a distance L is $t \approx \frac{L^2}{D}$, where D is the diffusion coefficient which depends on the molecular size and structure, viscosity of the medium, and the temperature. If $D = 100 \mu\text{m}^2/\text{s}$, a molecule takes about 2.78 h to propagate over a distance of 1 mm. Unlike a passive mode, the active mode of propagation directs the movements of molecules toward the targeted location. It is comparatively a faster process and takes fewer molecules thus suitable for inter-organ propagation scale. However, unlike passive modes, it requires propagation infrastructure and a constant supply of energy. Different forms of active transportation provide different propagation speeds such as motor proteins (e.g., kinesin, $2\text{--}4 \mu\text{m}/\text{s}$), bacterial chemotaxis (e.g., *E. coli*, few $\mu\text{m}/\text{s}$), and diffusion-reaction mechanism (e.g., calcium signaling, $20 \mu\text{m}/\text{s}$), etc. (Nakano et al. 2013). However, to support the information molecules, the propagation medium may contain some other types of molecules, such as transport molecules, to move information molecules, guide molecules to direct the movement of the transport molecules, interface molecules to selectively transport the information molecules, and address molecules to specify the receiver (Nakano et al. 2013).
- *Receiving and Decoding:* Receiving and decoding processes are done by the receiver nanomachine. Reception of information

molecules can be done through permeable plasma membrane, surface receptors, or chemically gated surface channels. The decoding process is essentially the reaction with the information molecule upon the reception at the receiving end. Furthermore, the consequences of the chemical reaction during decoding may generate movement, morphological changes, change in chemical functionality, or new molecules. The receiver may initiate multihop communication by releasing the produced molecules into the propagation medium (Nakano et al. 2013).

Communication Engineering Aspects

Although MC exists in nature for billions of years, the advancement in MC engineering has started primarily from the early 2000s. However, compared to traditional wireless communication, the advancement of MC is still in infancy (Farsad et al. 2016). This section sheds light on some of the engineering aspects of MC.

Physical Layer Aspects

The physical layer deals with the biophysical mechanism of data transmission, propagation, and reception. In essence, the data is transmitted in the form of IMs, also known as signal molecules. Moreover, the physical layer also provides the biophysical basis of hardware and interface (Farsad et al. 2016; Nakano et al. 2013).

- *Hardware:* The key hardware for MC are the sender, propagation channel, receiver, IM, and supporting molecules, as mentioned in Section “[Applications](#).” Essentially, these are all various kinds of bio-nanomachines.
- *Data/Message:* In a traditional WBAN, the physical layer data is transmitted into the form of 2.4 or 60 GHz mmWave (Anjum et al. 2017). Unlike traditional WBAN, the physical layer data or messages of MC are transmitted in the form of information molecules which

can be various kinds of protein molecules, vesicles, or bacteria.

- **Modulation Techniques:** Modulation in MC is the process of encoding data/messages in the IMs. The modulation or encoding of IMs can be done in various ways as we discussed in section “Applications.”
- **Propagation Channel Models:** Propagation channel models for intercellular and intracellular MC are known as microscale models. On the other hand, propagation channel models for inter-organisms are known as macroscale models. Major passive propagation models for microscale MC are free diffusion propagation and diffusion with first fitting. Major active propagation models are flow-assisted propagation, bacteria-assisted propagation, motor protein moving over microtubule tracks, microtubule filament motility over stationary kinesin, neurochemical propagation, and propagation through gap junction. The major macroscale propagation models are diffusion and flow-based propagation. Some other macroscale propagation models are advection, convection, mechanical dispersion, and turbulent flows. Macroscale models require comparatively larger amount of molecules and external source of power; hence, these models are active in nature (Farsad et al. 2016).
- **Noise Sources:** The sources of noise are primarily transmitter emission noise, random propagation, i.e., diffusion noise, reception noise, environmental noise such as degradation and reaction, multiple transmitters, etc.
- **Channel Capacity:** Practically, MC channels are not memoryless; thus, the channel capacity is different for different models of propagation. If x^n is a sequence of n successive transmission symbols, and y^n is the corresponding received symbols, then the channel capacity can be presented by Farsad et al. (2016):

$$\mathcal{C} = \liminf_{n \rightarrow \infty} \sup_{x^n} I(X^n; Y^n) \quad (1)$$

Link Layer Aspects

- **Error Handling:** To detect the transmitted message, the number of received molecules must be larger than a threshold. Hence, transmitting larger numbers of molecules increases the signal to interference plus noise ratio. Another approach of avoiding error is optimizing the transmission rate. Error detection and correction can be done by adding redundant information to the information molecule. For instance, adding an additional DNA sequence to a DNA molecule allows error detection and forward error correction at the receiving end (Nakano et al. 2012).
- **Addressing:** Addressing is the process of specifying the target receiver. Usually, addressing of the receiver is done by the type of molecule transmitted by the sender.
- **Synchronization:** Synchronization of the sender and receiver in MC is a complicated process because of the immense propagation delay and jitter. No significant research regarding synchronization is reported so far.
- **Media Access Control:** The interference among multiple pairs of senders and receivers can be avoided by transmitting different types of molecules for each sender-receiver pair. This technique is not sufficient for a large number of sender-receiver pairs. In that case, some other techniques could be employed such as channel reservation, switching or time-division multiplexing, etc. However, such approaches are not implemented yet.
- **Flow Control:** If the chemical reaction on the receiver side is significantly slower compared to the sender side, then the flow control is required to avoid buffer overflow on the receiver side. No such work has been reported yet in the literature.

Network Layer Aspects

The routing of the existing MC is limited to the static routing tables which fails to address dynamic locations of the network nodes. In case of a static routing, a sender transmits the data using a bacterium with addressing

molecules which indicates the target receiver. The router node receives the bacterium and employs statically defined chemical processes to retransmit the data using a bacterium which follows the chemical gradients to the following target router. Advancements regarding other network layer issues such as congestion control, topology management, network scalability, etc. are still limited (Nakano et al. 2013).

Mathematical Models

The simplest mathematical model to represent the movement of the information molecule is a random walk model which does not consider the directional drift or chemical reaction. Hence, a random walk model is suitable for representing passive propagation models. A more complex mathematical model is a random walk with drift which is suitable for representing the active propagation models where the movement of the IM is drifted directionally. Another kind of mathematical model for MC is the random walk with chemical reactions. This model considers the chemical reactions of IMs induced by the amplifiers. Amplifiers are located in the environment and react with molecules that can increase the reliability of the molecular propagation by multiplying the number of propagating molecules.

Applications

Although the primary application of molecular communication evolves around biomedical fields, its application in environmental and manufacturing fields is also reported (Nakano et al. 2012).

- *Biomedical Applications:* In the biomedical field, the applications of MC are health monitoring within an organism, disease diagnosis known as lab-on-a-chip, drug delivery within an organism, regenerative medicine, etc.
- *Environmental Applications:* MC can be used for monitoring and controlling environmental pollution.
- *Manufacturing Applications:* MC can be exploited to control the transport of bio-

nanomachines or molecules and can also be modified to develop novel patterns and structures of molecules (Nakano et al. 2013).

Conclusions

Although the concept of BAN² has been introduced in the early 2000s, the advancement of this research field is still at its infancy level, after two decades. However, BAN² has an immense potential and prospect in the biomedical and environmental applications. As a result, IEEE P1906.1 Standards Working Group for Nanonetworking has been formed in 2011 for standardizing the MC protocols.

Molecular Event Detection

Reza Mosayebi
Sharif University of Technology, Tehran, Iran

Synonyms

[Molecular abnormality detection](#); [Molecular anomaly detection](#); [Molecular target detection](#)

Definitions

Molecular event detection is one of the key challenges in many microscale revolutionary applications, such as environmental and health monitoring and disease diagnosis, which deals with detecting undesired signals at the nano- and microscales.

Historical Background

One of the key challenges in disease diagnosis and health monitoring applications is the problem of event detection, e.g., early tumor detection, which has received significant attention in

medicine and other related fields (Chen et al. 2016; Wuab and Qu 2015). Upon detecting tumor (event), a drug can be released at an appropriate rate to mitigate the effect of tumor (Chude-Okonkwo et al. 2017). This motivates the investigation of event detection at microscale using molecular communications.

Event detection has been extensively studied in different fields (Chandola et al. 2009). In this context, event is also referred to as abnormality, anomaly, and outlier which has several applications including failure detection in computer science, segmentation of signals in biomedical applications, and fraud detection for credit cards. However, in molecular communication systems, due to diffusion of molecules, the number of molecules received at a receiver (received signal) has Poisson distribution which imposes inherent randomness to the molecular channels. Due to this specific characteristic of molecular communication, classical methods cannot be directly applied for detecting molecular events. Therefore, several approaches have been proposed for molecular event detection (Felicetti et al. 2014; Okaie et al. 2016; Ghavami and Lahouti 2017; Nakano et al. 2017; Mai et al. 2017; Mosayebi et al. 2017). In all of the proposed works for molecular event detection, multiple nanosensors (NSs) for initial detection of event are employed. Upon detection, the NSs send their decisions via releasing an amount of molecules to a fusion center (FC) where the final decision regarding the presence of event is made. In particular, in Felicetti et al. (2014), it is assumed that mobile NSs move through the vasculature and gather at the target location by binding to a tumor. Next, in Okaie et al. (2016), a similar idea is used where two types of NSs are used, named leader and follower NSs. Here, leader NSs create an attractant gradient around the target. Then, follower NSs move according to the attractant gradient, approach the target, and perform necessary actions such as releasing drug. Employing static NSs is proposed for anomaly detection in body tissue in Ghavami and Lahouti (2017), Mai et al. (2017), and Mosayebi et al. (2017). In particular, in Ghavami and Lahouti (2017) a macroscale noise channel is considered between

the NSs and the FC, while in Mai et al. (2017) and Mosayebi et al. (2017), a microscale Poisson signal-dependent noise channel is considered. Finally, an abstract modeling and simulation of both static and mobile NS network for target detection is proposed in Nakano et al. (2017).

System Model

For molecular event detection, one can consider a network of M NSs that observe a part of a tissue or move inside the vasculature and sense their environment (sensing scheme), along with an FC. Upon detecting an event (target or abnormality), NSs will release an amount of molecules into the medium, where some of them may be collected by the FC (reporting scheme) and where the final decision regarding the presence of an event will be made. The absence and presence of event are denoted by hypotheses $\mathcal{H}_0$ and $\mathcal{H}_1$, respectively. In the following, the sensing and reporting schemes will be briefly described. Before going into the details of sensing and reporting schemes, it is noteworthy to mention that the approaches that will be described in the following are examples of what has been done in the molecular communication literature and are non-exhaustive for what might be practical.

Sensing Model

Each NS can measure one or more sensing variables, referred to as inputs. For instance, for tumor detection, examples of inputs include the concentration of specific types of molecules, referred to as *biomarkers*, such as nucleic acids and proteins, and a lack of oxygen (Wuab and Qu 2015; Chude-Okonkwo et al. 2017). Then, based on the measured inputs, the NS determines a numerical value which reflects the presence or absence of the event. For the sensing scheme, there are two different models in the literature, referred to as *hard* and *soft* decision schemes. For the hard decision scheme (Nakano et al. 2017; Ghavami and Lahouti 2017; Mai et al. 2017), the decision made by each NS $k \in \{1, \dots, M\}$ is a Bernoulli random variable (RV) C_k with the realization values of $c_k = 0$ and $c_k = 1$ upon

detecting hypotheses $\mathcal{H}_0$ and $\mathcal{H}_1$, respectively. However, for the soft decision scheme, one of the $L > 2$ values in $\mathcal{X} = \{0, 1/(L-1), 2/(L-1), \dots, 1\}$ can be assumed as a soft decision for the k -th NS, where small and large values of c_k indicate that NS k leans toward hypotheses $\mathcal{H}_0$ and $\mathcal{H}_1$, respectively (Mosayebi et al. 2017). For RV C_k under hypotheses $\mathcal{H}_0$ and $\mathcal{H}_1$, general probability mass functions (PMFs) $g_0(\cdot)$ and $g_1(\cdot)$, respectively, can be assumed, where under hard decision, i.e., $L = 2$, they have only two nonzero values for $c_k = 0$ and $c_k = 1$. It is noteworthy to indicate that the functionality of $g_i(\cdot)$, $i = 0, 1$ with respect to its argument is a function of several factors such as the NS structure and its sensing accuracy.

Reporting Model

For each sensor k , if $c_k \neq 0$, an instantaneously number (Ghavami and Lahouti 2017; Mai et al. 2017; Mosayebi et al. 2017) or a constant rate of molecules which can be degraded in the medium (Okaie et al. 2016; Nakano et al. 2017) will be released toward the FC. For each of the released schemes, a mean value of $g_i(c_k)\theta_k$ for the number of molecules released by the k -th NS and collected at the FC can be considered. Here, θ_k is a function of the number/rate of the released molecules, distance between the NS and the FC, the diffusion coefficient of the released molecules, and the shape and size of the FC. In line with the references for molecular event detection and for tractability of analysis, in the following it is assumed that $\theta_k = \theta, \forall k \in \{1, \dots, M\}$. Here, two cases can be imagined:

1. (Case I) Each NS sends a unique type of molecules, different from the molecules released by other NSs.
2. (Case II) The same type of molecule is used by all NSs.

In the following, for each case, the PMF of the signal received at the FC is modeled. Derived PMFs for the signal received at the FC will be further used to design optimal decision rule for the FC.

Case I

For Case I, since the types of molecules released by different NSs are different, the FC can distinguish between the messages sent by different NSs. Furthermore, an environmental noise for each type of molecules can be considered which is an independent source of molecules. Let Y_k denote the RV which models the number of released molecules by the k -th NS and the corresponding environmental noise present at the FC. Therefore, conditioned on hypothesis $\mathcal{H}_i, i = 0, 1$, the PMF of Y_k can be modeled as follows (Mosayebi et al. 2017, Eq. (8)):

$$P(Y_k = y_k | \mathcal{H}_i) = \sum_{c_k \in \mathcal{X}} g_i(c_k) \times \quad (1)$$

$$\frac{\exp(-g_i(c_k)\theta - \lambda_k) (g_i(c_k)\theta + \lambda_k)^{y_k}}{y_k!}, \quad (2)$$

$i = 0, 1,$

where $P(\cdot)$ denotes probability measure, y_k is a realization of Y_k , and λ_i is the mean number of the environmental noise molecules with the same type as the molecules released by NS k . Since the types of molecules are different, the RVs Y_k become independent. Now, by defining $\mathbf{Y} = [Y_1, \dots, Y_M]^T$ as the vector containing all RVs $Y_k, k \in \{1, \dots, M\}$, the PMF of the signal received at the FC can be characterized as follows:

$$P(\mathbf{Y} = \mathbf{y} | \mathcal{H}_i) = \prod_{k=1}^M P(Y_k = y_k | \mathcal{H}_i) \quad (3)$$

$$= \prod_{k=1}^M \sum_{c_k \in \mathcal{X}} g_i(c_k) \times \frac{\exp(-g_i(c_k)\theta - \lambda_k) (g_i(c_k)\theta + \lambda_k)^{y_k}}{y_k!},$$

$i = 0, 1,$

where $\mathbf{y} = [y_1, \dots, y_M]^T$ is a realization of $\mathbf{Y}$.

Case II

For Case II, since the types of molecules released by different NSs are the same, the FC cannot dis-

tinguish between the messages of different NSs. Therefore, the PMF of the number of molecules received at the FC is a function of RV $C = \sum_{k=1}^M C_k \in \mathcal{X} = \{0, 1/L - 1, 2/L - 1, M\}$. Since RVs C_k are statistically independent, the PMF of RV C can be obtained using convolution operator. This PMF is denoted by $G_0(\cdot)$ and $G_1(\cdot)$ for hypotheses $\mathcal{H}_0$ and $\mathcal{H}_1$, respectively. Furthermore, the same type of molecule can always be considered in the environment which plays the role of environmental noise. Therefore, by denoting the random variable Y as the total number of released molecules by different NSs and environmental noise that are collected at the FC, one can see that conditioned on hypothesis $\mathcal{H}_i, i = 0, 1$, Y can be modeled as follows (Mosayebi et al. 2017, Eq. (17)):

$$P(Y = y | \mathcal{H}_i) = \sum_{c \in \mathcal{X}} G_i(c) \times \quad (4)$$

$$\frac{\exp(-G_i(c)\theta - \lambda) (G_i(c)\theta + \lambda)^y}{y!}, \quad (5)$$

$i = 0, 1,$

where y is the realization of Y , c is the realization of C , and λ is mean number of environmental noise molecules.

Detector Design for the FC

For the FC, a decision $d \in \{0, 1\}$ is made, where $d = 0$ and $d = 1$ means that the FC chooses hypothesis $\mathcal{H}_0$ and $\mathcal{H}_1$, respectively. Due to the inherent randomness of the received signal and the presence of noise, the selected hypothesis by the FC may be incorrect. Therefore, two types of errors can be imagined: first, if the FC chooses $d = 1$, while hypothesis $\mathcal{H}_0$ is correct. For this case, the conditional probability of error is referred to as *probability of false alarm* and is denoted by $P_{fa} = P(d = 1 | \mathcal{H}_0)$. Similarly, another type of error exists where the FC chooses $d = 0$, while hypothesis $\mathcal{H}_1$ is correct. For this case, the conditional probability of error is referred to as *probability of missed detection* and is denoted by $P_m = P(d = 0 | \mathcal{H}_1)$.

For the FC, the goal is to design the optimal decision rule that minimizes the probability of missed detection subject to a pre-assigned upper bound ω on the probability of false alarm. That is,

$$\min_{\text{detectors}} P_m, \text{ subject to } P_{fa} \leq \omega. \quad (6)$$

The optimal solution of (6) is the Neyman-Pearson detector (Kay 1998), which compares the log-likelihood ratio (LLR) with the maximum threshold τ that ensures $P_{fa} \leq \omega$. The LLR for each mentioned cases above can be written as

$$\text{LLR} = \begin{cases} \sum_{k=1}^M \log \left(\frac{P(Y_k=y_k|\mathcal{H}_1)}{P(Y_k=y_k|\mathcal{H}_0)} \right); & \text{Case I,} \\ \log \left(\frac{P(Y=y|\mathcal{H}_1)}{P(Y=y|\mathcal{H}_0)} \right); & \text{Case II,} \end{cases} \quad (7)$$

where $P(Y_k = y_k|\mathcal{H}_i)$ and $P(Y = y|\mathcal{H}_i)$, $i = 0, 1$, are given in (2) and (5), respectively. Hence, the optimal decision rule can be written as

$$d_{\text{Optimal}} = \begin{cases} 0, & \text{if } \text{LLR} \leq \tau, \\ 1, & \text{if } \text{LLR} > \tau, \end{cases} \quad (8)$$

Remark 1 Since the general form of LLR in (7) may be computationally complex to be implemented in microscale, several approximations for LLR are proposed and investigated in Mosayebi et al. (2017).

Remark 2 In practice, for event detection, some system parameters such as θ and $g_i(\cdot)$, $i = 0, 1$ are not known for the FC. As a first step to address this, in Ghavami and Lahouti (2017), one unknown system parameter is assumed. For this case, in Ghavami and Lahouti (2017), the maximum likelihood estimation of the unknown system parameter is derived for the initial decision at the NSs. Then, based on the estimation, a suboptimal hard decision rule for the NSs is proposed and investigated.

Numerical Result

For a simple comparison between the proposed schemes, i.e., Cases I and II, the performance of Neyman-Pearson detectors is compared in Fig. 1 for

$$\begin{aligned} g_0(c_k) &= \frac{\exp(-2.5c_k)}{\sum_{x \in \mathcal{X}} \exp(-2.5x)}, \\ g_1(c_k) &= \frac{\exp(3.5c_k)}{\sum_{x \in \mathcal{X}} \exp(3.5x)}, \end{aligned} \quad (9)$$

$L = 4$, $M = 2$, and $P_{fa} = 0.05$. To this end, P_m is plotted versus θ for different values of λ . To have a fair comparison between Cases I and II, it is assumed that $\lambda_1 = \lambda_2 = \lambda$. From Fig. 1, it can be observed that as the value of θ increases, P_m decreases since the reporting scheme becomes more reliable. In addition, one can see that the relative performance of Case I and Case II depends on the value λ . For large λ ,

Molecular Event Detection, Fig. 1

Probability of missed detection versus θ for Cases I and II using the respective optimal decision rules for $P_{fa} = 0.05$. All curves were obtained via simulation

Case II outperforms Case I, whereas for small λ , Case I outperforms Case II. In fact, the advantage of Case II over Case I comes from the fact that the mean number of noise molecules for each type of molecule is assumed to be constant, i.e., $\lambda_1 = \lambda_2 = \lambda$, which leads to a higher overall noise for Case I compared to Case II. Alternatively, the trivial advantage of Case I over Case II is that the FC can distinguish between the molecules released by different NSs and exploit this additional knowledge for the improvement of the detection performance. Therefore, the superiority of Case I over Case II depends on the system parameters.

Future Directions

Although there are several works for molecular event detection, there exist some issues to be addressed. For instance, having a more adequate sensing model for particular applications such as event detection in blood vessels, body tissues, and air is highly recommended. The sensing model should be a function of the NS structure and the stochasticity of the event. In addition, considering more practical assumptions such as unknown sensing distribution, unknown locations for NSs, and unknown target location will result in different decision rules for the NSs and the FC. The idea of jointly estimation and detection which is introduced in the conventional communication systems can be also specialized for the molecular event detection systems.

Definitions

Multimedia is content composed of different types of digital objects such as text, audio, image, and video. Multimedia security addresses the protection of the intellectual property and the privacy of multimedia during acquisition, storage, processing, transmission, consumption, and disposal.

Historical Background

Advances in digital technologies have created significant changes in the way how multimedia is produced, distributed, marketed, and consumed. Typically, parties involved in multimedia business are *creator/owner*, *distributor*, and *consumer/user*. By preserving the security of multimedia, it is essentially protecting rights of all these parties. One notable milestone is the usage of Content Scramble System in the late 1990s, which is built on a stream cipher with 40-bit key, to protect commercially produced DVD discs by binding the content to a particular playback device (CSS 1996). It is later superseded by newer schemes such as the Content Protection for Recordable Media (CPR 2001) or the Advanced Access Content System (AAC 2005) due to low security strength. Similarly, the primary protection method for either the analog television or the digital television is encryption, such as VideoGuard (VG1 2012). The encryption system is built into the hardware of platform-supplied set-

top boxes so as to provide conditional access of the multimedia content. Additionally, it is common that the *creator* or *distributor* embeds a watermark-like logo in the broadcast content to increase brand recognition and assert ownership. The protection method used for online streaming television, such as the ones provided by Netflix and Hulu, is similar to dedicated terrestrial television, but this time the conditional access control is guaranteed by different technologies, such as the Common Encryption (CEN [2016](#)) and the Encrypted Media Extensions (EME) ([2017](#)). For example, the EME, recommended by W3C, provides copy protection of streaming content by providing a communication channel between web browsers and agent software.

All the abovementioned protection methods fit the centralized business model, where the *creator/distributor* plays the core role, but, driven by different technologies, e.g., cloud computing, IoT, healthcare personnel, and social networks, the business model itself keeps evolving. For example, the patient provides the health record to a hospital's server for personnel Medicare service, and people upload photos to Flickr and share them with friends. Under this decentralized scenario, there is no (strong) monetary incentive for *owners* to deploy a complex digital rights management (DRM) system, yet they still concern about privacy leakage. Despite the lack of direct monetary gain, the ubiquitous privacy concerns and users' unwillingness to participate continuously promote collaboration among legislative institution, industry, and academia to design new mechanisms to preserve the rights of different parties. For example, HIPAA ([HIP 1996](#)) regulates transactions of electronic healthcare data, Google's Encrypted BigQuery (EBQ [2015](#)) offers client-side encryption of user's query, and the prototype PIXEK (Pix [2018](#)) provides an end-to-end protection mechanism for their photos on the cloud.

Foundations

From the discussion above, the protection of multimedia, especially when the media object is with

low commercial value, requires the effort from law enforcement agency, coordination between different parties, and the appropriate usage of the technical measures. Here we mainly focus on technical measures, and the fundamental techniques used for multimedia security are discussed as follows.

Image/Video Source Identification

Image source identification aims to univocally link the image content to the device (i.e., camera) that captured it. Currently, the most promising technology to achieve this task exploits the detection of the sensor pattern noise (SPN) left by the acquisition device (Lukas et al. [2006](#)). This footprint is universal (i.e., every sensor introduces one) and unique (i.e., two SPNs are different even in case of images captured by cameras of the same brand and model). Machine learning techniques, such as support vector machine (SVM), are usually used to classify different image sources (cameras) according to the extracted features (fingerprints) of SPNs. For static images, SPN has been proven to be robust to common processing operations like JPEG compression (Lukas et al. [2006](#)). The photo response non-uniformity (PRNU) feature can be used for the case with severe compression (Milani et al. [2012](#)). However, compression and distortion in digital videos can usually increase the false-alarm probability. In addition, when considering video streaming over wireless networks, blocking and blurring effects caused by packet loss should be tackled for effective camera source identification. Detailed discussions can be found in Chen et al. ([2015](#)).

Digital Watermarking

Digital watermarking relies on the fact that multimedia data is noise-tolerant. It works by first imperceptibly embedding a unique watermark (fingerprint) into each copy of the considered multimedia content and then detecting the existence of the unique watermark from a suspicious copy. The research focus for watermarking is to investigate the trade-offs among embedding capacity, imperceptibility, and robustness. Most, if not all, digital watermarking systems are devel-

oped from the following two seminal designs: the spread spectrum system (Cox et al. 1997) and the quantization index modulation system (Chen and Wornell 2001). Detailed discussion about different digital watermarking systems can be found in Cox et al. (2007) and Barni and Bartolini (2004).

Format Compatible Encryption

Format Compatible Encryption (FCE) relies on the fact that multimedia data is always encoded and then stored under certain formats, such as WAV or MP3 for speech, JPEG or PNG for image, and WAV or MP4 for video. By modifying the behavior of encoder, FCE aims to make the syntax of encrypted data compliant with a standard decoder, i.e., it is decodable without decryption but suffered by (controllable) quality degradation. For authenticated users with the key, the joint encryption and encoding process can be removed without quality loss. For example, the JPEG compression of still images is composed by the DCT transformation, quantization, and Huffman coding processes. A FCE scheme for JPEG could be secretly shuffling or quantizing the transformation coefficients, as shown in Fig. 1. Detailed review of FCE scheme for multimedia data can be found in Stutz and Uhl (2012) and Massoudi et al. (2008).

Privacy-Aware Processing

Privacy-aware processing of multimedia data could rely on two different strategies: the one based on trusted execution environment and the one based on secure Multi-Party Computation (MPC). For the first class, representative technology includes Intel Software Guard Extensions (SGX) and AMD secure encrypted virtualization. For example, the work in Ohrimenko et al. (2016) presents a design that allows multiple hospitals to perform collaborative data analytics while guaranteeing the privacy of their patient datasets by using SGX. The MPC-based privacy-aware processing technology stems from the simple fact that all arithmetic operation can be expressed as a function of Boolean circuits, while Boolean circuit itself has a secured counterpart called Yao's Garbled circuit (Yao 1986). For example, Garbled circuit is used for server-side privacy-preserving image denoising (Zheng et al. 2017). Moreover, it is generally acknowledged that employing Garbled circuit, homomorphic encryption, and secret sharing to devise hybrid privacy-aware protocol for specific tasks will reduce cost and thus bring computation and bandwidth gain. Details about Intel Software Guard Extensions can be found in SGX (2015), and a MPC technique can be found in Lindell (2003).

Multimedia Security, Fig. 1 A FCE example on 512×512 image "Baboon": (a) Original image. (b) Standard JPEG decoding result when the 8 most significant DCT

coefficients are randomly permuted. (c) Standard JPEG decoding result when all the DC coefficients are encrypted

Key Applications

Multimedia security technology is a key-enabler for many businesses and services. The applications described below cover its typical usage.

- **Video Conferencing:** Video conferencing is a special way to conduct meetings; it allows users to communicate in real-time remotely so as to save a ton in travel cost. It is widely used to enable discussion on the most important perspectives of business right up to executive level. Possible security threats to video conferencing could be enormous, but the typical way to harden the security is to combine an identity-based access control policy and data encryption by deploying dedicated video conferencing systems, such as Cisco Webex or Skype for Business.
- **Online Streaming:** It is reported that Netflix, after hitting 50.85 million subscribers in 2016, has surpassed the total number of subscribers of all US cable companies. By shifting from cabled TV to streaming service, users are not restricted to special playback devices and able to enjoy content anytime anywhere. The secure multimedia streaming is commonly achieved by two mechanisms: using encryption to enforce conditional access control and using watermarking to deter pirates distribution. Beside technical measures, law enforcement has been advocated by *creators/distributors* under this centralized business model. For example, in a recent response to a call from NTIA, MPAA suggests criminal charges against online video piracy and coordination between a broad range of online service providers (MPA 2018).
- **Privacy-Preserving Multimedia Processing:** Hosting or contributing personal data to a public server for personalized service becomes popular due to the maturity of artificial intelligence and cloud computing. In this case, content *owners* are likely to be individuals and the value of a single piece of data is not high but the whole dataset is the key to success of

many businesses. For example, recommender systems collect and analyze user's past behavior and decisions to generate recommendations. Since privacy leakage could happen at any stage of the life cycle of multimedia data, it essentially requires imposing protect to data acquisition, storage, processing, transmission, consumption, and disposal.

Definitions

Multiple access is the technique that multiple signals simultaneously access the same terminal, i.e., a base station, or one terminal simultaneously transmit multiple signals to different user terminals. Different resources, i.e., time, frequency, code, etc., can be assigned to different signals to avoid or reduce the multiple access interferences (MAC).

History Background

During the last decades, multiple access technique has been widely used in mobile communications and provided increasable capability and various services, i.e., from traditional voice to multimedia communications, as shown in Fig. 1. It plays a fundamental and important role in cellular networks.

A cellular always includes one base station (BS) and many users that are located in its coverage. And the coverage area of one cellular is generally determined by the transmit power of its BS and mathematically expressed as a hexagon, as shown in Fig. 2. There are two basic conceptions, one is uplink transmission and the other is downlink transmission. Uplink transmission means that many users transmit their signals to the BS, and downlink is the opposite processing that the BS simultaneously transmits signals to the multiple users. And multiple access is a technique that is used to reflect both uplink and downlink access processing.

The multiple access technology is always viewed as one of the most important techniques for cellular wireless communications. With the

increasing of data rates, the multiple access technology updates correspondingly.

There are lots of works that have been done on this topic, from the first-generation (1G) frequency-division multiple access (FDMA), the second-generation (2G) time-division multiple access (TDMA), the third-generation (3G) code-division multiple access (CDMA) (Adachi et al. 2005; Schulze and Luders 2005) to the fourth-generation (4G) orthogonal frequency-division multiple access (OFDMA). The evolution of multiple access techniques has pushed for a rapid advancement of wireless communications. Recently, many researchers believe that, for the coming fifth generation (5G), it will be non-orthogonal multiple access (NOMA) era.

Classification

FDMA

Frequency-division multiple access (FDMA), as its name, utilizes frequencies to divide different users, and each user is allocated a carrier frequency. It is noted that an extra frequency band

Multiple Access Technique for Cellular Wireless Networks, Fig. 1
The development of wireless communications

Multiple Access Technique for Cellular Wireless Networks, Fig. 2

A diagram of cellular networks

is necessary between any adjacent frequencies, to reduce the sidelobes' interferences. For downlink, different users occupy different frequencies; therefore the BS can realize simultaneous transmission. For uplink, there is no multiple access interference (MAI) among different users, since each user occupies its respective frequency. A diagram of FDMA is shown in Fig. 3a.

There are two major advantages of FDMA, one is that it is easy to realize and the other is there is no MAI. The disadvantages are also obvious, for example, it occupies a wider frequency bandwidth, leading to a lower spectrum efficiency (SE). It is interesting to design filters to reduce sidelobes, i.e., filter bank. If there is only a few users and there are enough frequency resources, FDMA is a promising technique.

TDMA

Time-division multiple access (TDMA) is similar to the FDMA case, which explores time instead of frequency to distinct different users, as shown in Fig. 3b. The major difference between TDMA

and FDMA is that the synchronization is very important for TDMA. Without accurate time synchronization, there will be serious MAI among users, and even the performances of the whole system can be destroyed. Thus, many works have been done on the synchronization problem of TDMA.

CDMA

Code-division multiple access (CDMA) is widely used in 3G system, in which every user occupies the same time and frequency, and users are separated by different spreading sequences/vectors, as shown in Fig. 3c. Each user is assigned a spreading sequence/vector, and these spreading vectors are expected to be orthogonal to each other. The classical structure is named as direct-sequence (DS)-CDMA; besides this basically one, there are generally two approaches: single-carrier (SC)-CDMA and multicarrier (MC)-CDMA, as shown in Figs. 4 and 5, respectively (Adachi et al. 2005). Both SC- and MC-CDMA can flexibly provide variable-rate transmissions, with retaining multi-

Multiple Access Technique for Cellular Wireless Networks, Fig. 3 A diagram to show the features of FDMA, TDMA, and CDMA

ple access capability. Actually, OFDM is a special case of MC-CDMA when the spreading factor is one.

The SC-CDMA and MC-CDMA, respectively, explore time-domain and frequency-domain spreading (chip-level spreading is used for further discussion). At the transmitter, after the binary information data is modulated, the data-modulated symbols are then spread, time domain spread for SC-CDMA, and frequency domain spread for MC-CDMA. Without/with IFFT processing for SC-/MC-CDMA, the processed signals insert GI and then transmit to the channels.

At the receiver, frequency-domain equalization (FDE) can be used to improve the BER performances. It has been proved that the use of minimum mean square error (MMSE) weight can provide the best BER performances among various FDE weights, since the MMSE weight can provide the best compromise between the noise enhancement and suppression of frequency-selective fading channels. Simulation results show that MC-CDMA with MMSE-FDE provides much better BER performances than SC-CDMA with traditional coherent rake combining. It has been derived that SC-CDMA with proper FDE, instead of the traditional rake combining, can achieve good BER performances that are comparable to MC-CDMA.

For uplink CDMA systems, different users' signals are asynchronously arrived at the BS via different fading channels, leading to seri-

ous MAIs, which limit the uplink capacity. The capability of MAI suppression achievable with pure CDMA is not sufficient. It is an important research topic to suppress the effect of MAI. There are many interesting methods, such as multiuser detection (MUD), soft-iterative multistage receiver, etc.

In papers (Liu and Adachi 2006; Yu et al. 2013, 2014), two-dimensional (2D) block spread CDMA is proposed, which can be applied to solve the MAI and achieve frequency diversity gain in frequency-selective fading channels. The 2D block spread CDMA consisted of chip-level and block-level spreading, and they are implemented as different roles. The chip-level spreading plays the same part as traditional SC-/MC-CDMA, which can achieve frequency diversity gain by using MMSE-FDE in the receiver. In 2D block spread CDMA, block-level spreading is performed to each block after chip-level spreading. Before the transmission, the GI, which is larger than or equal to the maximum delay among different users, is inserted. At the receiver, after removing the GI, block-level de-spreading is performed in order to remove the MAI. If the maximum timing offset among users is within the GI length, perfect removal of MAI is possible in the case of block fading, i.e., the channel stays constant during at least one block. Both chip-level spreading codes and block-level spreading codes can be constructed using the orthogonal variable spreading factor code tree. The 2D block SC-CDMA and MC-CDMA are given in Figs. 6 and 7.

modulation and demodulation, respectively, and “FDE” means frequency-domain equalization

IDMA

Interleave-division multiple access (IDMA) is also an interesting multiple access scheme, which was proposed in Ping Li et al. (2006) by Prof. Li, as shown in Fig. 8. Actually, IDMA and CDMA work in a similar way, both of which occupy all the same time- and frequency-domain to transmit data information. There are several differences between IDMA and CDMA, such as: (1) in CDMA, transmit symbols are modulated by different spreading sequences/vectors to distinguish different users, whereas IDMA exploits different interleavers to separate different signals, and (2) at a receiver, de-spreading is used to recover transmitted signals in CDMA, while iterative algorithm, just like decoding algorithms for low-density parity-check (LDPC), is used in IDMA. IDMA can be flexibly applied in different modulations and channel conditions.

OFDMA

Orthogonal frequency-division multiple access (OFDMA) or orthogonal frequency-division multiplexing (OFDM) is one of the most appreciated multiple access schemes. Actually, OFDM has been widely used in 4G; WLAN, i.e., IEEE 802.11a/g; and digital audio and video broadcasting (DAB, DVB) systems. It also uses orthog-

onal subcarriers to separate users; however its bandwidth is much smaller than the FDMA case. And it doesn't need extra bandwidth to avoid the effect of sidelobe. Generally speaking, a subcarrier's spectrum of an OFDM symbol is the Fourier transform of a rectangular window of symbol duration T_s , which is a sinc-function with zeros at $\frac{1}{T_s}$. And the centers of other carriers are put in these zeros; thereby, the subcarriers are orthogonal to each other, as shown in Fig. 9.

DAB always explores COFDM (coded OFDM), in which the data transmitted on the subcarriers is protected by forward error correction (FEC) coding. COFDM also allows different groups of bits to be protected with a different strength code rate. Considering the subcarriers are subject to flat fading, interleaving can be used to improve the bit error rate (BER) performance of OFDM. For an OFDM system, interleaving is generally classified as time and frequency interleaving or random and regular interleaving.

An OFDM modulator mainly consists of two parts: IDFT (inverse discrete Fourier transform) and guard interval (GI) that is also called cyclic prefix (CP), as shown in Fig. 10. The IDFT makes OFDM practically feasible. And we don't need many filters and oscillators any more. In reality,

Multiple Access Technique for Cellular Wireless Networks, Fig. 8 A diagram of IDMA transmitter and receiver given in Ping Li et al. (2006)

$$\text{where } x_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} X_k e^{j2\pi nk/N}, n = 0, 1, \dots, N-1$$

Multiple Access Technique for Cellular Wireless Networks, Fig. 9 A diagram to show the spectrum of OFDM signals

the actual processing utilizes IFFT (inverse fast Fourier transform) instead of IDFT.

The GI (or CP) should be larger than, or at least equal to, the maximum multipath delay. Hence, it can avoid the inter-symbol interferences (ISI) caused by the multipath delay. The GI can efficiently avoid the effect of ISI; however, it will decrease the throughput of an OFDM

system. Therefore, some papers (Liu et al. 2017a) try to remove GI, with acceptable detection complexity.

There are lots of papers focusing on OFDM system, from synchronization, nonconstant power envelope, to the channel estimation, etc. For the synchronization issue, the frequency-domain nature of OFDM makes the effect of

several synchronization errors to be explained with the properties of DFT (discrete Fourier transform). In fact, OFDM synchronization functions can be performed either in time or frequency domain, which is different from the traditional single-carrier systems. To decrease the effect of asynchronization, low sidelobes of OFDM symbols are appreciated. Filtered multitone (FMT) modulation is a useful scheme, which is a kind of filter bank implementation of multicarrier system (Proakis 2009).

Another major problem of OFDM is relatively high PAPR (peak-to-average power ratio) issue. In general, the large signal peak occurs when the signals in the sub-channels add constructively in phase. Such large signal peaks may result in clipping of the signal voltage in a DAC (digital-to-analogue converter), when the OFDM signal is synthesized digitally. It may saturate the power amplifier, leading to the intermodulation distortion. To avoid the PAPR problem, there are generally two kinds of methods. One is exploring distortion methods, i.e., clipping, filtering, peak cancellation, etc.; and the other is exploring the methods without distortion, for example, selective mapping, partial transmit sequence, etc (Proakis 2009).

Figure 10 shows the implementation of an OFDM symbol. After passing through IFFT processor, the values are fed to DACs. And the low-pass filtered signals of the real and imaginary streams are amplitude modulated onto RF carrier and then added together and sent through a band-pass filter (BPF) to the transmit antenna.

NOMA

Non-orthogonal multiple access (NOMA) explores the same resource block to serve different users, thus transfers information of multiple users superposition (Ding et al. 2017; Dai et al. 2015). It is different from orthogonal multiple access (OMA), which assigns orthogonal resources to different users. Owing to the orthogonal feature, different signals can be separated without MAI. However, the spectrum efficiency (SE) of OMA schemes is low.

NOMA can improve SE by overloaded information, which can be realized in power domain, by different modulation amplitudes, and/or code domain, via multidimensional constellation codebooks. Therefore, the core of all the emerging multiple access techniques is to optimally combine modulation and coding techniques to support high spectrum efficiency.

Nowadays, the multiple access schemes of 5G need to support massive users of both human and machines. High SE multiple access schemes become emergency. Many novel multiple access techniques have been proposed, such as power-domain NOMA, sparse code multiple access (SCMA), pattern division multiple access (PDMA), multiuser shared access (MUSA), etc. Compared to the well-known OMA schemes such as OFDMA, NOMA provides improved SE by transmitting overloaded information in the same time resources or frequency resources (Ding et al. 2017; Dai et al. 2015).

Power-domain NOMA allocates different power to different users according to their different channel state information (CSI). In general, a user with better CSI is assigned a small power; in contrast, a user with worse CSI is assigned a large power to keep fairness. And successive interference cancelation (SIC) algorithm is utilized at the receiver to decode the superimposed signal in sequence. Power-domain NOMA is easy to realize with low complexity, and it is applicable for Internet of Things networks.

SCMA, which was first proposed in 2013 (Nikopour and Baligh 2013), can also be viewed as a type of NOMA technique, which works based on traditional DS-CDMA technique, as shown in Fig. 11. Its input binary bits first pass through a modulator to map the binary bits to complex symbols, and then direct sequence spreading is performed to all mapped complex symbols. Compared to the DS-CDMA, SCMA combines modulation and spreading, and thus it can achieve shaping gain of multidimensional constellations due to its optimal SCMA codebook design (Nikopour and Baligh 2013; Nikopour et al. 2014; Zhou et al. 2017).

Definition

Multiple access techniques allow multiple terminals to share the common communication medium based on multiplexing. The multiplexing is provided in the physical layer, and the shared communication medium can be wired cables or wireless spectrum. The availability of the communication medium is limited, for example, limited frequency band and limited time. Therefore, multiple access techniques are essential to maintain successful communication among multiple devices. The basic well-known multiple access techniques are frequency division multiple access (FDMA), time division multiple access (TDMA), code division multiple access (CDMA), and spatial division multiple access (SDMA). A class of non-orthogonal multiple

access (NOMA) techniques has recently gained much interest. The control mechanism to distribute channels to users is also known as medium access control (MAC).

Historical Background

The applications of the multiple access techniques present in every generation of wireless communication systems. In the first US analog cellular system, AMPS (Advanced Mobile Phone System) is based on FDMA. TDMA and CDMA dominate in the second-generation (2G) wireless communication systems. For example, in GSM (Global System for Mobile communication), TDMA is adopted for distinguished users, while the CDMA is adopted in IS-95 (Interim Standard 95) systems. The varieties of multiple access techniques based on TDMA and CDMA have been widely adopted in ad hoc sensor networks. CDMA becomes the dominant multiple access technique in the third-generation (3G) wireless communication systems, with the prevailing worldwide standards known as CDMA2000, WCDMA (Wideband CDMA), and TD-SCDMA (Time Division – Synchronous CDMA). In fourth generation (4G), the hybrid multiple access techniques, including orthogonal FDMA (OFDMA), TDMA, and SDMA, are preferred in multiple-input multiple-output (MIMO) systems (Miao et al. 2016). With the increase of the MIMO size, massive MIMO, also known as large-scale MIMO, together with millimeter wave communications, becomes one of the promising techniques in fifth-generation (5G) wireless communication systems (Marzetta 2010; Dai et al. 2015; Sun et al. 2015). In massive MIMO, the SDMA techniques, for example, BDMA (beam division multiple access), are recently studied in Sun et al. (2015).

Foundations

The standard FDMA, TDMA, and CDMA techniques can be further illustrated in Fig. 1. As it is shown in Fig. 1a, when FDMA is adopted,

Multiple Access Techniques, Fig. 1 Illustration of FDMA/TDMA/CDMA techniques

the system bandwidth is divided into several narrowbands, with nonoverlapping frequency slots, (i.e., the adjacent frequency bands are separated by a guard band). Usually, in a FDMA system, each user occupies a pair of frequency bands (i.e., frequency division duplexing (FDD)). One is for forward channel (downlink), and the other is for the reverse channel (uplink). FDMA was the initial multiple access technique for cellular systems. An advanced form of FDMA is the orthogonal frequency division multiple access (OFDMA), which is shown in Fig. 2. In OFDMA, each user is assigned a subset of subcarriers, and the low-complexity fast Fourier transform (FFT) operations can be used at both the transmitter and receiver side in the system (Miao et al. 2016).

In TDMA systems, the data frame is segmented into nonoverlapping time slots, separated by guard space. When the time slot is assigned to a user, the user takes up the entire frequency band for data transfer. An advanced form of TDMA is dynamic TDMA (DTDMA), where different time slots may be assigned to the same user according to the scheduling algorithm. For example, the user terminal may use the first time slot for the first data frame but use another time slot for the next data frame. DTDMA usually works with MAC protocol to randomly access the shared channel. Common examples for DTDMA include the slotted ALOHA in GSM systems (initial access stage for users) and carrier sense multiple access with collision avoidance (CSMA/CA) in IEEE 802.11. An example of the slotted ALOHA can be illustrated in Fig. 3 (Tanenbaum 2003). In slotted ALOHA, the time frame is divided into equal size slots. The data packet from each user is transmitted at the beginning of next slot. If collision occurs, retransmitted packet will select future slots with probability p , until successful. Specifically, in Fig. 3, collisions occur in the first and third slot, while packets 1, 2, and 3 from each user are successfully delivered in the second, sixth, and fifth slot, respectively. DTDMA schemes have been widely in ad hoc networks since the channel can be randomly accessed.

The CDMA scheme is based on spread-spectrum code. Signals from different users are

Multiple Access Techniques, Fig. 2 OFDMA block diagram

Multiple Access Techniques, Fig. 3 Slotted ALOHA, C collision, S successful, E empty

Multiple Access Techniques, Fig. 4 Illustration of BDMA

transferred simultaneously over the same carrier frequency. At the receiver side, the user signal is separated by cross-correlation of the received signal with each possible code sequence. Two typical forms of CDMA are the direct sequence spread spectrum (DSSS) and the frequency-hopping spread spectrum (FHSS) (Miao et al. 2016). The CDMA scheme is known to have low signal-to-noise ratio (SNR) working region, which indicates lower transmission power is required in the system. The near-far problem is a serious one in CDMA systems.

SDMA utilizes the spatial separation of the users to fully use the frequency spectrum. In Fig. 4, an example of SDMA techniques, i.e., BDMA is illustrated (Sun et al. 2015). As it is shown in Fig. 4, multiple beams are generated by using the phased array antennas. SDMA has been

one of the promising multiple access techniques for 5G.

Besides the orthogonal multiple access techniques, a class of NOMA schemes is also discussed for 5G (Dai et al. 2015). NOMA accommodates multiple users through non-orthogonal resource allocation. Generally, NOMA can be implemented via power or code domain multiplexing. Examples of NOMA schemes are power-domain NOMA, multiple access with low-density spreading code, sparse code multiple access, multiuser shared access, and so on (Dai et al. 2015).

Key Applications

Multiple access techniques are fundamental in wireless communication systems, including cellular networks, ad hoc networks, and vehicular networks, for multiple user terminals to access the shared common medium.

Definition

A nanonetwork is a set of interconnected nanomachines, i.e., devices that integrate nanometer-scale components, with computing, data storing, sensing, and actuation capabilities. Nanonetworks are expected to expand the capabilities of single nanomachines both in terms of complexity and range of operation by allowing them to coordinate, share, and fuse information. Nanonetworks enable new applications of nanotechnology in the biomedical field, environmental research, military technology, and industrial and consumer goods applications.

Historical Background

Nanotechnology and biotechnology are providing the engineering community with a new set of tools to control matter and program functions at the atomic and molecular scale. At this scale, novel nanomaterials, structures, and systems show new properties that cannot be realized at the microscopic level. By leveraging such properties, devices with unprecedented applications can be developed. Among others, nanosensors and nanoactuators, able to both monitor and control

physical, chemical, and biological processes at the nanoscale, have been realized (Wu and Qu 2015).

The realization of nanomachines with computation, data storage, and communication, in addition to sensing and actuation capabilities, is enabling transformative applications of nanotechnology in diverse fields (Akyildiz et al. 2008). By means of communication, nanomachines will be able to complete more complex tasks in a distributed manner. In addition, the integration of resulting nanonetworks with macronetworks and eventually the Internet leads to the ultimate cyberphysical systems, known as the Internet of Nano Things (Akyildiz and Jornet 2010) and the Internet of Bio-Nano Things (Akyildiz et al. 2015).

There are three paths toward developing nanomachines and enabling the communication between them, namely, *nanomaterial-based nanoscale electromagnetic networks*, *biomolecular communication networks*, and *hybrid nanonetworks*. Next, the state of the art is reviewed, and open challenges are identified for each approach.

Nanomaterial-Based Nanoscale Electromagnetic Networks

From Nanomaterials to Nanomachines

Nanomaterials are materials with any external dimension in the nanoscale (sizes range from approximately 1–100 nm) or having internal structure or surface structure in the nanoscale. Among others, graphene (Ferrari et al. 2015), a one-atom-thick planar sheet of bonded carbon atoms in a honeycomb crystal lattice, has been and still is one of the most popular nanomaterials. Graphene exhibits very unique mechanical, electrical, and optical properties. Among others, it is the world's thinnest and lightest material while being harder than diamond; it is a very good conductor with very high electron mobility; and, despite being one atom thick, it can absorb light efficiently. Graphene is the first of a kind, but not the only two-dimensional material. As

of today, more than 100 2D nanomaterials have reported, including molybdenum disulfide (MoS_2) (Splendiani et al. 2010) or hexagonal boron nitride (hBN) (Giovannetti et al. 2007), with different electronic properties. Moreover, the combination of different nanomaterials can lead to new nanostructures with novel properties (Geim and Grigorieva 2013).

By utilizing nanomaterials and the tools provided by nanotechnology, the different components which integrate a nanomachine (Fig. 1) can be realized, specifically,

- **Nano-processor** This is enabled by the development of smaller transistors. While 22 and 14 nm channel length transistor technologies are already commercial, the smallest transistor to date is based on a thin graphene strip made of just 10 by 1 carbon atoms, i.e., less than 1 nm long (Ponomarenko et al. 2008).
- **Nano-memory** Single-atom memories are at the basis of ultracompact data storing in nanomachines. For the time being, different single-atom memories based on different physical principles have been demonstrated, including electronic memories (Pla et al. 2012) and optical memories (Specht et al. 2011).
- **Power Nano-generator** In addition to nano-batteries (Brazier et al. 2008), energy-harvesting nano-systems or power nano-generators are needed for nanomachines to be able to continuously operate. Different energy-harvesting systems have been demonstrated to date, including mechanical energy harvesting through devices (Wang et al. 2017) or EM energy harvesting (Gadalla et al. 2014).
- **Nanosensor and Nanoactuator** Physical, chemical, and biological nanosensors and nanoactuators have been developed by using graphene and other nanomaterials. These are able to detect and measure magnitudes at the nanoscale, including the physical characteristics of structures just a few nanometers in size or the presence of biological agents such as virus or cancerous cells (Wu and Qu 2015).

Nanonetworks, Fig. 1 Conceptual architecture of a nanomachine

- Nano-transceiver and Nano-antenna**
 Nanomachines require miniature transceivers and antennas to communicate. On the one hand, noble metals can be utilized to fabricate plasmonic nano-antennas, which are just hundreds of nanometers in length and can efficiently operate at infrared and visible optical frequencies (Nafari and Jornet 2017). These require similarly small nano-lasers (Feng et al. 2014) and nano-photodetectors (Luo et al. 2016) to operate. On the other hand, graphene can be utilized to fabricate miniature nano-transceivers (Jornet and Akyildiz 2014b) and nano-antennas (Jornet and Akyildiz 2013), which can efficiently operate in the terahertz (THz) band (0.1–10 THz), i.e., at a frequency much lower than their metallic counterparts. These bring many opportunities for communication in nanonetworks, as it is explained next.

Besides the fabrication of each one of the components, there are several challenges related to their integration in a single device. While self-assembly techniques, including DNA scaffolding (Maune et al. 2010), are being developed, the utilization of a single nanomaterial or arrangement of nanomaterials to fabricate the

different components at once will drastically simplify the realization of nanomachines.

Terahertz and Optical Nanoscale Communication

The very small size of nano-antennas imposes the use of very high frequencies for EM wireless communication among nanomachines, ranging from the THz band to the infrared and visible optical frequency bands. This introduces multiple challenges and opportunities for communication and networking:

- Channel Modeling** There are three main phenomena which affect the propagation of EM waves at THz band and optical frequencies, namely, spreading, absorption, and scattering. Common to any wireless communication system, the *spreading loss* refers to attenuation due to the expansion of the wave front as it propagates through the medium. The *scattering loss* refers to the signal loss due to redirection (reflection, diffusion) of EM waves as they propagate through a medium with obstacles, which depends on the obstacle size in terms of wavelength. At THz frequencies, the main problem is posed by molecular absorption (Jornet and Akyildiz 2011; Han et al. 2015), whereas at optical frequencies, scattering is the main challenge

to overcome (Johari and Jornet 2018). In both cases, the channel can support beyond multi-GHz transmission bandwidths.

- **Physical Layer** The capabilities of nanomachines and the peculiarities of the channel need to be taken into account when designing the physical layer. In terms of *modulation*, the transmission of 100-femtosecond-long pulses spread in time has been proposed as a way to enable ultra-broadband communication in nanonetworks (Jornet and Akyildiz 2014a). These pulses have their main frequency components in the THz band (between 0.5 and 4 THz), can be generated with nano-transceivers, and are already widely used in THz sensing applications. Similarly, new *channel coding* strategies are needed to overcome channel errors resulting from weak signals, noise, and multiuser interference, such as low-weight channel codes (Jornet 2014). Independently of the modulation and coding strategy, physical-layer synchronization is a major bottleneck to overcome, due to the very low power and very short duration of the symbols.
- **Link Layer and Above** The very large available bandwidth at THz and optical frequencies reduces the need for the nodes to contend for the channel. However, the energy fluctuations, due to the use of energy-harvesting systems, require the development of link-layer synchronization and *medium access control (MAC)* algorithms for both ad hoc and infrastructure nanonetworks (Wang et al. 2013). Moreover, the very large number of nanomachines in nanonetworks requires the development of new *addressing* schemes, beyond IPv6, which leverage the hierarchical nature of nanonetworks and built upon compressed-addressing concepts. In addition, due to the limited transmission range of nanomachines, *multi-hop relaying and routing* strategies need to be developed (Pierobon et al. 2014; Tsioliariidou et al. 2015). Ultimately, ensuring *end-to-end reliability* will require the revision of well-established concepts at the transport layer.

Biomolecular Communication Networks

Bio-nanomachines

Bio-nanomachines are uniquely identifiable basic structural and functional units that operate and interact within the biological environment. Stemming from biological cells, the basic units of life, and enabled by synthetic biology and nanotechnology, they are based on the control of biological processes (Akyildiz et al. 2015). Biotechnology, through DNA sequencing and synthesis tools, is enabling the reading and writing of cells' genetic code (Kahl and Endy 2013), providing open access to the set of structural and functional instructions at the basis of life. At the same time, nanotechnology is expanding these directions toward the assembly of artificial cells (Wu and Tan 2014).

The different components of a bio-nanomachine can be abstracted from the main components of a biological cell (Fig. 2) as follows:

- **Bio-Nano Processor** This corresponds to the molecular machinery that, from the DNA molecules (contained in the nucleus) to the so-called transcription and translation (at the ribosomes), generates protein molecules with instruction-dependent types and concentrations.
- **Bio-Nano Memory** This is an abstraction of the chemical content of the cytoplasm, i.e., the interior of the cell, comprised of molecules synthesized by the cell as a result of DNA instructions, and other molecules or structures, e.g., vesicles, exchanged with the external environment, and organelles, including the nucleus in case of eukaryotic cell, as shown in Fig. 2.
- **Bio-Nano Power Source** This is the reservoir of adenosine triphosphate (ATP) molecule, which is synthesized by the cell from energy supplied from the external environment in various forms, and provides the chemical energy necessary for the cell biochemical reactions to

Nanonetworks, Fig. 2 Main components of a eukaryotic cell (with nucleus) and their abstraction as components of a bio-nanomachine

take place. In the case of eukaryotic cells, ATP production occurs in mitochondria.

- **Bio-Nano Sensing and Actuation** This corresponds to the capability of a cell to chemically recognize external molecules or physical stimuli, e.g., light or mechanical stress, and to change the chemical characteristics of the environment or mechanically interact through moving elements, such as flagella, pili, or cilia.
- **Bio-Nano Transceivers** These are abstractions of specific chains of chemical reactions, i.e., signaling pathways, through which cells exchange information with each other and the environment.

Biomolecular Communications

Individual biological cells and cell populations perceive, elaborate, and exchange information through the propagation of molecules and their chemical reactions (Payne and You 2014), which can be abstracted according to the paradigm of molecular communication

(MC) (Akyildiz et al. 2011). The heterogeneity of biological MC mechanisms and the fundamental differences with respect to classical communication scenarios pose the following unique challenges and opportunities for the realization of bio-nanomachine interconnections into MC networks:

- **Channel Modeling** Several different MC mechanisms can be observed in nature that do not behave as the channels previously considered when engineering communication systems. In particular, the peculiarities of channels based on the simplest mechanism of molecular diffusion in terms of path loss and signal distortion (Pierobon and Akyildiz 2010), and their associated noise sources (Pierobon and Akyildiz 2011; Noel et al. 2014), necessitated completely novel interference (Pierobon and Akyildiz 2011), channel estimation (Jamali et al. 2016), and channel capacity (Pierobon and Akyildiz 2013; Atakan and Akan 2010) analyses. Other simple MC mechanisms have been

considered, such as molecular motors (Moore et al. 2006), gap junctions (Nakano et al. 2007; Kilinc and Akan 2012; Barros et al. 2015), and chemotaxis (Gregori and Akyildiz 2010), along with more complex MC scenarios, such as the cardiovascular system (Chahibi et al. 2013), while more fundamental communication theoretical aspects related to molecular information have been treated in Akan et al. (2017).

- **Physical Layer** The design of physical links between bio-nanomachines has to take into account different options to realize information encoding and modulation in MC systems, along with their theoretical performance (Lu et al. 2015; Murin et al. 2017), and molecular mechanisms to optimize signal detection and decoding (Kilinc and Akan 2013; Mahfuz et al. 2014, 2015; Chou 2015; Li et al. 2016; Jamali et al. 2018). Ultimately, the peculiarities of the underlying biological cells and the tools for their engineering should be accounted for. In this direction, synthetic-biology-enabled analog communications have been studied in Pierobon (2014) while digital-like communications in Unluturk et al. (2015). Channel coding strategies adapted to the efficiency of analog processing in cells have been suggested in Marcone et al. (2017).
- **Link Layer and Above** The definition of network architectures and protocols on top of the aforementioned biological MC systems will be particularly challenging given the nonlinear nature of many biochemical phenomena (Mian and Rose 2011) and the shared nature of the media, such as fluids (Deng et al. 2017). Optimization in terms of energy consumption for information propagation within these networks will be also an important aspect (Qiu et al. 2017), since cells have limited resources. A further challenge will be the interconnection of heterogeneous networks, i.e., composed of different types of bio-nanomachines and/or based on different biological MC mechanisms. The realization of interfaces between the electrical domain and the

biochemical domain will be the ultimate frontier to create a seamless interconnection between the biological environment and the Internet.

Hybrid Nanonetworks

Beyond nanomaterial-based nanomachines or synthetically engineered living cells, hybrid nano-bio-engineered nanomachines and nanonetworks will exhibit unique capabilities and enable applications, even yet to be envisioned. Among others, *optogenetics*, i.e., the use of light to control and monitor genetically engineered living cells, is at the basis of fundamental studies in developmental and neurodegenerative diseases as well as of brain machine interfaces, which can restore and even enhance functional abilities and cognition (Wirdatmadja et al. 2017). Beyond optogenetics, *optogenomics*, i.e., the control of gene expression with light, can lead to unprecedented control of biological processes. For all these, hybrid nanomachines, able to manipulate and interact with electromagnetic (THz, optical) and molecular signals, need to be developed.

Key Applications

The potential applications of the nanonetworks can be classified in four main areas: *biomedical applications*, including intrabody health monitoring and drug delivery systems, immune system support mechanisms, and artificial biohybrid implants; *industrial and consumer goods applications*, development of intelligent functionalized materials and fabrics, new manufacturing processes and distributed quality control procedures, and food and water quality control systems; *environmental applications*, biological and chemical nanosensor networks for pollution control, biodegradation assistance, and animal and biodiversity control; and *military applications*, nuclear, biological, and chemical defenses and nano-functionalized equipment and human enhancement.

Definition

Nanoscale terahertz communications refer to the wireless technology that enables the exchange of information and coordination between nanomachines in the electromagnetic frequency range spanning from 100 GHz up to 10 THz.

Historical Background

Nanotechnology is providing the engineering community with a new set of tools to create miniature machines, just a few cubic micrometers in size, with sensing, actuation, computation, and data storing capabilities (Ferrari et al. 2015). By

means of communication, such nanomachines will be able to accomplish more complex tasks in a distributed manner. Nanonetworks (Akyildiz et al. 2011), i.e., networks of nanomachines, enable transformative applications in the biomedical, environmental, security, defense, and consumer field. While different communication technologies are being considered to enable nanonetworks, in this entry, the focus is on the use of electromagnetic (EM) signals at THz-band frequencies.

Why Communication in the Terahertz Band?

Enabling nanoscale EM communication requires the development of nanoscale transceivers and antennas. The miniaturization of a metallic antenna would impose the use of very high resonant frequencies. For example, a 1-micrometer-long dipole antenna would expectedly resonate at 150 THz, i.e., in the near infrared. However, at infrared and visible optical frequencies, metals do not behave as perfect electric conductors (PEC) anymore, and thus, common assumptions in antenna theory need to be revised (Dorfmueller et al. 2010; Nafari and Jornet 2017). Moreover, in addition to the antenna, optical nano-transmitters (e.g., nano-lasers) and optical nano-receivers (e.g., nanophotodetectors) will be needed to enable nanoscale optical communication. Even when those become available, the very high propagation loss at optical frequencies combined with the limited power of nanomachines can compromise the feasibility of nanonetworks.

To overcome these limitations, graphene can be utilized to develop novel nano-transceivers and nano-antennas able to operate at lower frequencies than their metallic counterparts. Graphene is a two-dimensional carbon crystal that has excellent electrical conductivity, making it very well suited for propagating extremely high-frequency electrical signals (Ferrari et al. 2015). Moreover, graphene supports the propagation of THz surface plasmon polariton (SPP) waves at room temperature (Koppens et al. 2011; Vakil and Engheta 2011). SPP waves are surface-confined EM waves that appear at the interface of a metal (graphene

in this case) and a dielectric (air or any other substrate on which graphene is deposited). The propagation properties of SPP waves, which can be electronically tuned, determine the behavior of graphene-based plasmonic nano-devices.

In Jornet and Akyildiz (2010, 2013), the use of graphene to build plasmonic nano-antennas was proposed for the first time. The fundamental idea is to leverage the reduced propagation speed of SPP waves on graphene to design resonant antennas which are physically small but equivalently electrically large. As a result, a 1-micrometer-long nano-antenna, just tens to hundreds of nanometers wide, can efficiently radiate at frequencies in the THz band, i.e., at a frequency two orders of magnitude lower than metallic antennas with the same size. In successive works, it has been shown that the resonant frequency of the antennas can be electrically tuned (Tamagnone et al. 2012), and different shapes and designs have been considered (Dragoman et al. 2015).

In addition to the nano-antenna, mechanisms to generate, modulate, detect, and demodulate the THz signals are needed. Different mechanisms have been considered to date. In Jornet and Akyildiz (2014b), a THz plasmonic signal source and detector based on a hybrid graphene III–V semiconductor HEMT was proposed. Compared to existing plasmonic sources and detectors, the generated plasma wave is not directly radiated but utilized to launch an SPP wave on the graphene layer that extends toward the nano-antenna. Other options include the use of photoconductive antennas, which downconvert optical radiation into THz-band radiation (Yardimci et al. 2015), plasmonic grating structures (Otsuji et al. 2013), or quantum cascade lasers (Lu et al. 2016). For all these, the THz band is envisioned as the frequency band of communication of nanomachines.

Terahertz-Band Channel Modeling

Characterizing the THz channel is a necessary step toward enabling nanoscale THz communications. While the frequency regions immediately below (i.e., microwave and millimeter-wave) and above (i.e., infrared and visible optical) this band have been extensively investigated, this

is one of the least-explored frequency bands in the EM spectrum. In Jornet and Akyildiz (2011), the first channel model for the entire THz band was developed, by utilizing tools from radiative transfer theory, electromagnetics and communication theory, and leveraging the contents of the high-resolution transmission molecular absorption (HITRAN) database. There are two main phenomena affecting the propagation of EM signals at THz frequencies in free space, namely, spreading and molecular absorption. The *spreading loss*, which is common to any wireless communication system, accounts for the attenuation due to the expansion of the wave as it propagates through the medium, and it depends only on the signal frequency and the transmission distance. The *absorption loss* accounts for the attenuation that a propagating wave suffers because of molecular absorption, i.e., the process by which part of the wave energy is converted into internal kinetic energy in some of the molecules that are found in the medium. This depends on the concentration and the particular mixture of molecules encountered along the path. Different types of molecules have different resonant frequencies, and in addition, the absorption at each resonance is not confined to a single frequency but spread over a range of frequencies. As a result, the terahertz channel is very frequency selective. A complete list of absorption-defined spectral windows is provided in Fig. 1, with carrier frequency f_c , 3-dB bandwidth B_{3dB} , molecular absorption loss A_{abs} , and total path loss A , over the distances at 0.1, 1, and 10 m. While, for long distances, the effort is currently on characterizing individual transmission windows (e.g., 300 GHz Priebe et al. 2011), it is clear that for nanoscale THz communications, the entire THz band can be considered as a single transmission window.

The presence of obstacles further complicates the propagation of THz waves. Any object whose size is beyond a few wavelengths (i.e., a few millimeters or more) behaves as an obstacle for THz signals, which can be reflected, scattered, or diffracted, leading to multipath propagation. In this direction, a unified multi-ray channel

are shown in the top figure (w_{11} is missing due to its high absorption loss), while complete windows are listed in the bottom table

model for the THz band was first provided in Han et al. (2015), based on ray tracing techniques and accounting the propagation models for the line of sight (LoS), reflected, scattered, and diffracted paths. The developed theoretical model was validated with the experimental measurements at 60 and 300 GHz from the literature. Then, using the developed propagation models, an in-depth analysis on the THz channel characteristics is carried out, in terms of the distance-varying and frequency-selective spectral windows, coherence bandwidth, wideband channel capacity, and the temporal broadening effects. The principles to develop efficient multi-ray model are summarized here. When LoS is available, the direct ray dominates the received signal energy, while the reflected rays play a dominant role when LoS is absent. As the operating frequency increases, the surface is seen to be rougher, and hence, more power is scattered out of the specular direction. Hence, scattered rays are very important and have to be included in the ray tracing model for both LoS and NLoS conditions. Furthermore, the diffraction path can be ignored in general, only except when the receiver is in

the very closed region near the incident shadow boundary. Further stochastic modeling studies are presented by Hossain et al. (2017) and He et al. (2017).

Communication Mechanisms

The very large bandwidth supported by the THz-band channel over short distances enables new modulation strategies, which are also well suited for the limited capabilities and energy constraints of nanomachines. For example, ultra-low-energy sub-picosecond-long pulses can be utilized. These pulses, whose major frequency components are between 0.5 and 4 THz (see Fig. 2), are already being used in several applications such as THz spectroscopy and imaging systems. In this direction, TS-OOK, a new communication scheme based on the transmission of 100-femtosecond-long Gaussian pulses by following an on-off keying modulation spread in time, was first proposed in Jornet and Akyildiz (2014a). In this scheme, a logical “1” is transmitted by using a 100-femtosecond-long pulse, and a logical “0” is transmitted as silence, i.e., the device remains silent when a logical

Nanoscale Terahertz Communications, Fig. 2 Time and frequency responses of a femtosecond-long pulse for THz-band communications

zero is transmitted. To benefit from this transient behavior of molecular absorption and account for the temporal broadening effect, the time between symbols needs to be much longer than the pulse duration (e.g., a few tens of picoseconds), and, for convenience, it is a fixed parameter in the proposed scheme. Note that under TS-OOK, many nano-devices can simultaneously transmit without creating interference. Indeed, due to the fact that the time between transmissions is expectedly much longer than the pulse duration, several nanomachines can concurrently use the channel without affecting each other. To fully exploit this phenomenon, low-weight channel coding strategies have been proposed (Jornet 2014).

Furthermore, as an extension from the carrierless to the carrier-based modulation scheme, a multi-wideband waveform design for distance-adaptive THz-band communications is developed by Han et al. (2016), which includes the features of the pseudorandom time-hopping sequence and the polarity randomization. To cope with the unique characteristics and improve the distance, the pulse waveform design in the distance-adaptive multi-wideband system for the THz band includes the development of the waveform model and the dynamical adaptation of the rate and the transmit power on each sub-window. An optimization framework is formulated to solve these design parameters, with the aim is to maximize the communication distance while satisfying the rate and the transmit

power constraints. Accurate synchronization for these ultra-short pulse communications is critical, for which a low-sampling-rate (i.e., fraction of Nyquist rate) timing acquisition algorithm is proposed, by extending the theory of sampling signals with finite rate of innovation in the communication context and exploiting the properties of the annihilating filter (Maravic and Vetterli 2005; Han et al. 2017). Interference and coverage analysis based on stochastic geometry method are studied (Yao et al. 2017), taking into account the nanonetwork density, THz frequency band, and interference strength.

Network Protocols

The interconnection of nanomachines with existing wireless communication networks and ultimately the Internet (Akyildiz and Jornet 2010) requires the development of nano-micro interface devices, to bridge the nanoscale and micro-scale systems.

Networking protocols for nanoscale THz networks need to take into account the capabilities of nanomachines and the peculiarities of the THz channel. At the link layer, the very large bandwidth provided by the THz channel and the intrinsic multiuser interleaving ability of TS-OOK simplifies the regulation of the channel access. Nevertheless, energy limitations of nanomachines introduce many other challenges. In this direction, an energy and spectrum-aware medium access protocol for

nanoscale networks was proposed (Wang et al. 2013), to achieve fair, throughput, and lifetime optimal channel access by jointly optimizing the energy harvesting and consumption processes. In particular, the maximum allowable ratio between the transmission time and the energy harvesting time is derived, below which the nano-nodes can harvest more energy than the consumption, theoretically enabling perpetual data transmission. By utilizing the elasticity of the inter-symbol spacing of the pulse-based physical layer, multiple nano-nodes can transmit packets in parallel without causing transmission collisions, which forms a symbol-compression scheduling algorithm. In addition, a receiver-initiated MAC protocol for nanonetworks was presented in Mohrehkesh and Weigle (2014). Still at a very early stage, routing in nanonetworks requires further attentions.

Key Applications

- **In vivo health monitoring and drug delivery systems** Nanosensors can be implanted to operate inside the human body in real time and provide fast and accurate disease diagnosis. Furthermore, autonomous nanorobots can be used to serve drug delivery and even minimally invasive surgery (Elayan et al. 2017).
- **Nuclear, biological, and chemical defenses** Chemical and biological nanosensors can be used to detect harmful chemicals and biological weapons in a distributed manner, by precisely sensing the concentration as low as one molecule.
- **The Internet of Nano-Things** The interconnection of nanoscale machines with existing communication networks and ultimately Internet defines a truly cyber-physical system which known as the Internet of Nano-Things (IoNT) (Akyildiz and Jornet 2010), as one step forward from the Internet of Things.
- **Wireless network-on-chip (WiNoC) communications** The THz band can provide efficient and scalable means of inter-core communication in WiNoC networks, by using planar nano-antennas to create ultra-high-

speed links. More importantly, the use of graphene-based THz band communication (Abadal et al. 2013) would deliver inherent multicast and broadcast communication capabilities at the core level.

NB-IoT

Definitions

The Narrowband Internet of Things (NB-IoT) is a major feature enhancement toward massive machine-type communications (mMTC) addressed in the Third Generation Partnership Project (3GPP) working group, which targets on devices requiring low data rate, low cost, and long battery life.

Historical Background

With the evolving toward a connected world with the Internet of Things (IoT), low-power wide-area (LPWA) network is developed to support devices that have low power consumption, low mobility, and long range. The LPWA category

includes both standardized and proprietary wireless technologies; NB-IoT is one of them standardized by the 3GPP. NB-IoT was first introduced by 3GPP Release 13 in June 2016. The performance enhancements in Release 13 (3GPP TR 45.820 [2017](#)) include (1) about 55,000 devices per cell under the suggested service model, (2) 164 + dB of coverage, (3) 10 or more years of battery life, and (4) latency in 10 s. In addition to legacy long-term evolution (LTE) service requests, NB-IoT defines control and user plane optimization for more efficient application data transmission (3GPP TS 23.401 [2017](#)). In 2017, the 3GPP Release 14 provides further enhancements in power efficiency, multicast support, and positioning.

Foundations

NB-IoT is designed to coexist with GSM and LTE systems in three operation modes. In the in-band mode, an LTE physical resource block (PRB) is used as a narrowband to transmit signaling and traffic data. In the guard-band mode, NB-IoT channels operate in the guard bands of LTE physical channels. In the standalone mode, the re-farmed GSM low-frequency bands, such as 700, 800, and 900 MHz, are used by NB-IoT. For the downlink transmission, NB-IoT adopts the orthogonal frequency-division multiple access (OFDMA) technology with 15 kHz subcarrier spacing like LTE. For the uplink transmission, the single-carrier frequency-division multiple access (SC-FDMA) technology is adopted supporting 15 and 3.75 kHz carrier spacing for single-tone and multitone transmissions, respectively. Frequency-division duplex technology with the half-duplex transmission is used to separate uplink and downlink frequency bands (3GPP TS 36.211 [2017](#)).

The NB-IoT radio resources are arranged into radio frames in the time domain and channels in the frequency domain. A radio frame consists of ten 1-ms-long subframes, and an NB-IoT channel contains 12 subcarriers reutilizing the LTE PRB structure. At the same time, physical channels

and signals are explicitly designed for narrow-band access (3GPP TS 36.213 [2017](#)).

For the downlink, three physical channels are defined to carry user data and control messages:

- Narrowband Physical Broadcast Channel (NPBCH) broadcasts the master information block (MIB) with system information. NPBCH occupies the first subframe of every radio frame consuming 10% of downlink resources.
- Narrowband Physical Downlink Control Channel (NPDCCH) carries UE-specific downlink control information (DCI) for data transmission, paging, and random access. The specification of NPDCCH is indicated by parameters $R_{\max}$ (the maximum DCI repetition number) and G (a system parameter).
- Narrowband Physical Downlink Shared Channel (NPDSCH) delivers user and signaling data to a specific UE in transport blocks. The size of a transport block is determined by the used modulation and coding scheme (MCS) and the transmission time length. A transport block can span across multiple subframes.

Signals used for cell search and synchronization are Narrowband Primary Synchronization Signals (NPSS) and Narrowband Secondary Synchronization Signals (NSSS). NPSS uses 11 subcarriers in the 6th subframe of every radio frame; NSSS carries the cell identity and information in the last subframe of every even radio frame. An eNB also transmits the System Information Block-NB (SIB-NB) through NPDSCH for extra system information not carried in MIB. For the uplink, there are two physical channels defined:

- Narrowband Physical Random Access Channel (NPRACH) is for eNB to receive random access preambles from UEs with single-tone 3.75 kHz subcarrier spacing.
- Narrowband Physical Uplink Shared Channel (NPUSCH) delivers user data and signals from a specific UE to the eNB using one of the two

formats. NPUSCH format 1 carries user data in single-tone or multitone tones. NPUSCH format 2 carries the acknowledgment (ACK) and negative ACK (NACK) of a Hybrid Automatic Repeat reQuest (HARQ) process.

Based on the radio resource specification, the NB-IoT system performs scheduling to determine the transport block size and the timing of NPDSCH and NPUSCH. The scheduling process takes into account received service data units and pre-allocated physical resources. NPDCCH carries scheduling parameters in DCI formats to the corresponding UE. Therefore, NB-IoT HARQ process, which completes a round of transport block transmission, sequentially transmits a DCI, transport blocks, and an ACK/NACK in the end. The HARQ in NB-IoT is both adaptive and asynchronous. There are five critical scheduling parameters.

- Resource assignments are the numbers of resource units assigned to the transport block.
- MCS index is to indicate the selected MCS. The combination with resource assignment determines the amount of data carried in a transport block.
- Repetition number is the number of transmission repetition applied to transport blocks. In NB-IoT, the radio uses repetition coding for error correction.
- Scheduling delay is the number of subframes to be postponed after DCI before transmitting transport blocks.
- Subcarrier indication specifies the number and location of used subcarriers affecting the duration of a transport block.

DCIs are defined in three formats: The DCI format N0 carries NPUSCH scheduling grants containing resource assignment, MCS index, repetition number, scheduling delay, and subcarrier indication. The DCI format N1 carries the scheduling control for NPDSCH and preambles for NPRACH contention free procedures, which contains scheduling parameters and the ACK resource index of the HARQ process. The DCI format N2 carries NPDSCH paging and

direct indication messages. A UE monitors predefined NPDCCH search spaces to detect the DCI messages. The NPDCCH period is the interval between two consecutive NPDCCH and is equal to $R_{\max} \times G$ subframes long. Allocation of NPDCCH essentially determines the frequency of scheduling opportunities (Huang et al. 2018).

The 3GPP TR 45.820 (2017) defines three levels of coverage enhancement (CE) achieved by repetition coding allowing up to 2048 repetitions. Normal CE0 is the level providing coverage similar to legacy General Packet Radio Service (GPRS). Robust CE1 provides about 10 dB improvement over CE0; Extreme CE2 provides about 20 dB improvement over CE0. The achieving target maximum coupling loss for CE0 to CE2 is 144, 154, and 164 dB, respectively.

To accomplish application data transmission procedures involving multiple transport blocks, NB-IoT supports three modes: legacy LTE service request, control plan optimization, and user plane optimization. The control plan optimization, which provides mobile-terminated (MT) and mobile-originated (MO) procedures, is the major lightweight protocol introduced below.

NB-IoT runs the MT procedure to send a data packet from the core network to a UE in the Radio Resource Control (RRC) idle state. After the paging process, the MT procedure sequentially schedules the following messages between the UE and an eNB:

1. Preamble. The UE sends a preamble signal to eNB to initiate the random access.
2. Random access response (RAR). RAR carries the response to the preamble and the grant of the next message.
3. RRC connection request. UE sends the connection request using uplink resources pre-allocated in RAR.
4. RRC connection setup. The eNB then schedules the setup information using the downlink to complete the random access process.
5. RRC connection setup complete. The uplink message from the UE establishes the RRC connection.

6. Downlink information transfer. After the RRC connection is established, the MT downlink data packet transmission begins.

For the MO procedure sending data from UE to core network, the first four messages are for the random access process as the same as the MT procedure. However, the RRC connection setup complete message carries the uplink data packet.

Key Applications

The mMTC is one of essential usage scenarios of the Fifth Generation (5G) systems (3GPP TR 38.913 2017) in the context of IoT. The NB-IoT is expected to be one of the extensively deployed technologies for mMTC. In this case, low data rate and low device cost applications ranging from smart city, smart building, environmental sensing, and consumer electronics can be well supported.

Definitions

The neighborhood-based ICT-driven support (NIS) system of emergency medical services (EMS) delivers efficient and interdisciplinary home care to elderly people in hyper-aged societies. The NIS system consists of five major components: (1) distributed NIS networks; (2) NIS slave node, an efficient sensing device; (3) NIS master node; (4) IoTtalk, an IoT device manager; and (5) NIS controller for EMS. Figure 1 illustrates an overview of the NIS system for elderly people.

Since many elderly people may not want to access new or advanced ICT technologies (e.g., smartphone or computer), the system should be designed as simple and automated as possible. Take the following community as an example, where each elderly's residence is no more than 50–100 m away from each other. We consider two types of elderly peoples. One is the cared elderly people who are older than 70 years old or are in poor physical conditions. The other is the caregiver elderly people who are younger (i.e., 60–65 years old) and healthier and is willing to use ICT products. The caregiver elderly people are responsible for regular care of cared elderly people.

Since the cared elderly people may not want to use ICT products, at the cared elderly people's place, a simple mobile device (i.e., the smartphone with Wi-Fi communication capability) is deployed, which is treated as an NIS slave node. The NIS slave node consists of applications which can report the health condition and collect data from the motion sensors at the cared elderly people's residence. The short-range device-to-device (D2D) communication technology is applied for relaying the data to the NIS controller via the NIS slave nodes. At the caregiver elderly people's residence, more advanced ICT technologies are deployed. A robot is treated as the NIS master node at the caregiver elderly people's residence. The robot is installed with intelligent functionalities and can monitor and have functionalities to work with the caregiver elderly people. In other words, the robot can "care of" the caregiver elderly people.

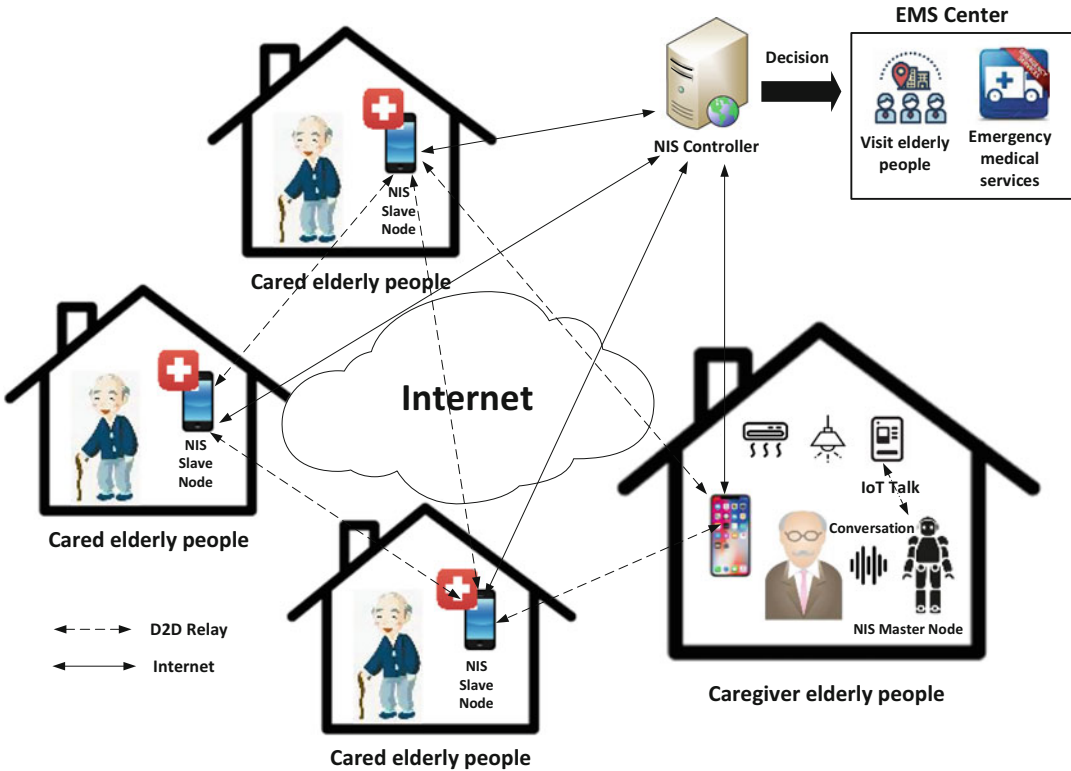

The concept of "community neighborhood" is that the elderly people (both cared and caregiver) who live in the same neighborhood can take care of each other. When abnormal activities from cared elderly people are detected, the caregiver elderly people are informed, and he could make a phone call or visit the cared elderly people personally for checking. The NIS master node has intelligence to assist caregiver elderly people to analyze and observe health condition of cared elderly people.

The health and medical monitoring data is transferred to the NIS controller for long-term and follow-up checking health condition of elderly people. An intelligent decision-maker in the NIS controller can determine the urgency of the cared elderly people. Then, the NIS controller could send an alert to EMS center for triggering any corresponding procedures to give aid to the cared elderly people. With the support of the NIS system, the emergency notification and response time of treatment for the elderly people can be drastically reduced, such that the situation of the lonely death could be avoided.

Historical Background

The world is aging rapidly. For example, the effect of aging is evident in both Japan and Taiwan. Japan is the most aged country in the world with more than 20% of its population over 65 years old. It is estimated that the number will reach 30.3% in 2025 and climb to 36.1% in 2040 ([Statistics Bureau](#)). Fourteen percent of Taiwanese people are anticipated to become over 65 years old in 2017, 20% in 2025, and more than 40% in 2060 ([Policy for long-term care: Ministry of Health and Welfare](#)).

Japan's policies are moving toward to having livelihood support services paid for something other than long-term insurance. In Japan, social security cost has exceeded 25% of the national income ([Ministry of Finance](#)). This could become the biggest cause of financial collapse, making conversion of existing long-term care policies come with a pressing issue. Furthermore, it is known that the number of lonely deaths (e.g.,

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 1 An overview of NIS system

persons who live alone die without being noticed by anyone) of elderly people in Japan has been increasing in recent years (McDonald 2012).

Smart environments (e.g., smart home) often try to be aware of the user locations, situations, and lifestyles and try to provide proper services. For example, the system can automatically control home electrical appliances based on the home situation. The air conditioner may be turned on (or turned off) automatically based on the location and intention of the user. The intention of the user can be estimated based on the user's daily activity patterns. In addition, it is possible to avoid crisis by detecting the abnormal activities. In such circumstances, it is an important issue to build an efficient and effective community-based system in hyper-aged societies.

The neighborhood-based ICT-driven support (NIS) system for emergency medical services (EMS) fulfills the requirements of the elderly people care.

Foundations

A rise in the aging population increases the pressure on the social security and homecare industry to provide the necessary care. The IoT technology could be one solution to reduce the cost to resolve the issue.

The IoT allows different IoT devices connected to the Internet to work together without human invention. In the NIS system, the NIS master node can retrieve monitoring data from the NIS slave node. Analysis (e.g., machine learning technologies) on such information can help to know how cared elderly people behave in the daily life. Furthermore, if any behavior anomaly is detected, the caregiver can be informed first, and an alert could be sent to the EMS centers (e.g., 119 in Taiwan). Following that, a standard EMS service can be provided to the cared elderly people efficiently and effectively. Compared with the traditional EMS service, such a system can

speed up the whole procedure of the EMS service.

The NIS system consists of a robust communication infrastructure, simple NIS slave node for data collection, intelligent NIS master node, efficient devices management, and intelligent decision-maker for EMS response.

In the following, we illustrate the technologies that can be used in the five major components in the NIS system.

Distributed NIS Networks

The distributed NIS networks provide connectivity between the smartphones of the elderly residences by exploiting the Relay-by-Smartphone technology (Kang et al. 2007; Nishiyama et al. 2014, 2015a; Ito et al. 2013). Relay-by-Smartphone is a technology realizing device-to-device (D2D) communication by using the already available Wi-Fi on smartphones.

As shown in Fig. 2, it relays messages from device to device by employing the technologies of Wi-Fi Direct and delay-tolerant network (DTN) (Kawamoto et al. 2013; Takahashi et al. 2013, 2014; Oiyama et al. 2014).

When the device can find a neighboring device around it, it can send the messages soon by using Wi-Fi Direct. On the other hand, when it is unable to find a neighboring device, it keeps the messages for a while and sends it after finding the

other device(s) or fixed infrastructures with DTN. It can be harnessed as a communication method in the locations where the network infrastructure such as cellular systems and open access points of the Internet are not available, for example, in rural areas, islands, mountainous areas, and so forth. The Relay-by-Smartphone technology is adopted to connect elderly residences in an isolated area for early detection of the occurrence of an emergency. In the hyper-aged societies, it is anticipated that the number of elderly residences without adequate communication tools increases, which causes many problems such as solitary deaths. Relay-by-Smartphone can provide a cheap yet effective communication scheme without fixed infrastructure because old and used smartphones are sufficient to install the application of the Relay-by-Smartphone.

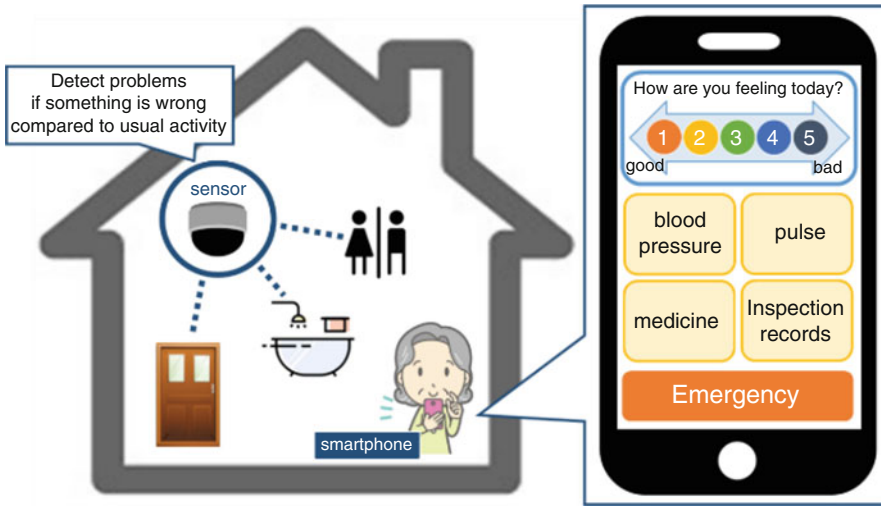

A network is constructed between the IoT sensors and smartphone of each elderly residence to collect and deliver the elderly people's health status and other monitored information over the Relay-by-Smartphone-based distributed network.

NIS Slave Node

Two applications are provided by the NIS slave node as shown in Fig. 3. One is for reporting the health conditions of the elderly people. It is operated on the smartphone as a simple application, for example, having buttons for reporting

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 2 The overview of the constructed network based on Relay-by-Smartphone

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 3 An overview of NIS slave node

the health condition on a five-point scale. It can be customized to include more inputs like blood pressure and pulse and whether they are taking medicines or not, according to the situation of each elderly people. Elderly people push the button by themselves at a certain time of everyday. By using this, the system can monitor the change of the health condition of elderly people and analyze what kind of procedure is required for them. In addition, the application can be used for reporting the occurrence of an emergency situation. By pushing the emergency button, they easily notice the situation to neighborhoods and emergency units.

The other application is using the motion sensor at the elderly residence. The motion sensor monitors the daily motion of elderly people such as opening and closing of the door of restroom, entrance of the house, and so forth and sends the information via the constructed network in Topic1. The system learns the usual motion of each elderly people and detects problems if something is wrong compared to usual activity based on the learning and reported information from the sensor.

NIS Master Node

The NIS master node performs two major functions. First, it collects the data from the NIS slave

node at the cared elderly people's place and analyzes the monitoring data to build the behavioral model for the cared elderly people, which is used to detect any abnormal behavior of the cared elderly people. If such an event is detected, it will inform the caregiver elderly people to check the status of the cared elderly people and send out an alert to the EMS centers if necessary.

Second, the NIS master node monitors the activities of the caregiver elderly people and can have simple interaction with the caregiver elderly people. For example, if it is too hot indoor, the NIS master node can turn on the air conditioner for the caregiver elderly people. Figure 4 illustrates the system architecture of the NIS master node, NIS controller, IoT device management, and IoTalk. The related works that have been proposed on robot technology for daily healthcare of elderly or disabled people can be found in Nishiyama et al. (2015b), Kim et al. (2009), Pung et al. (2009), and Kudo (2012).

In the NIS master node, an autonomous robot can execute homecare tasks: reminding elderly people to take medicines, measuring the physiological information, and monitoring the activity of the elderly people. The functional module of the NIS master node is shown in Fig. 5. Some commercial robots (e.g., ZenboTM

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 4 Framework of NIS master node, NIS controller, and IoT device management

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 5 Functions of the NIS master node

(Ahn et al. 2017)) are based on Android Software Development Kit (SDK) (<https://zenbo.asus.com/developer/documents/Zenbo-SDK-Getting-Started/Getting-Started>), and the system developer can implement the features with application programming interfaces (APIs) provided by the robot manufacturer.

To summarize, an NIS master node (see Fig. 4 (1)) serves as an intelligent robot, which consists six main function modules detailed below:

(A) Voice control interface serves as the interface for the users to control the behavior of the robot. The voice recognition techniques are

applied to let the robot understand the intentions from the caregiver elderly people and execute the corresponding instructions.

- (B) Communication function consists of Wi-Fi and Bluetooth communication functions. The robot can communicate with the IoT devices or the NIS slave node directly.
- (C) IoT device function controls the IoT devices based on the IoTtalk API (Lin et al. 2015). This function enables interaction between the devices and sensors in the house.
- (D) Motion detection function monitors and detects possible abnormal behaviors by checking the activities of elderly daily living (ADL) (Crepeau 2003; Suzuki et al. 2006).

- (E) Emergency service function enables the caregiver elderly people to be able to issue an order to the NIS master node to trigger the emergency medical service when cared elderly people are in emergency situation.
- (F) Vital data analysis function performs vital data sensing at home, which includes blood pressure (using sphygmomanometer with Bluetooth), blood sugar level (using blood glucose meter with Bluetooth), body temperature, and so on. Analysis (e.g., machine learning technologies) on such information can help to know how cared elderly people behave in the daily life.

IoT Device Management for NIS System

The NIS system adopts the IoTtalk technology (also known as IoT EasyConnect system) (Lin et al. 2015) to manage IoT devices. An IoT device is characterized by its “features” (e.g., temperature, vibration, and display) that are manipulated by the network applications. If a network application handles the individual device features independently, a software module can be implemented for each device feature, and the network application can be simply constructed by including these brick-like device feature modules. Based on the concept of device feature, the applications and interactions for homecare equipment are easily created.

The IoTtalk technology is adopted to manage the environment devices at the caregiver elderly’s home (see Fig. 4 (2)). For instance, when the sensor detects an elderly people’s step length has become short, the IoTtalk may control other facilities at home to initiate appropriate response (e.g., switching on the light, recommending the use of a cane through home audio/visual system, and so forth).

Intelligent Decision-Maker at NIS Controller

An intelligent decision-maker is installed at NIS controller (see Fig. 4 (3)), which uses the AI technology (e.g., machine learning) to analyze the health and medical data collected from the elderly people. According to the data processing by the intelligent decision-maker, we may classify three

categories of abnormal situations: (1) critical, (2) urgent but stable, and (3) general and stable. An optimal processing algorithm uses the collected sensor inputs to determine whether any abnormal situation occurs.

Key Applications

The key application where the NIS system can be applied is the emergency medical services (EMS) also known as ambulance services or paramedic services. Figure 6 shows a general case of triggering the corresponding EMS management. The dispatch center receives each type of alarm and then reacts different responses properly according to the corresponding category (Lin et al. 2015). The NIS has two major types of EMS responses: (1) by EMS ambulance and (2) by other mobile unit other than EMS ambulance (Ng et al. 2017; Ringh et al. 2015; <http://www.pulsepoint.org/pulsepoint-respond/>; https://www.scdf.gov.sg/content/scdf_internet/en/community-and-volunteers/mobile_phone_technology.html). EMS ambulance only responds for two categories of situation: (1) critical and (2) urgent but stable.

There are often two levels of EMS ambulance, ALS (advanced life support) and BLS (basic life support). Only ALS team is capable of providing intravenous resuscitating medication, endotracheal intubation, and manual defibrillation. ALS ambulance would be reserved for the “critical” cases, which often imply patients with unstable vital signs, and BLS ambulance would be utilized for the “urgent but stable” cases (Lin et al. 2015). To reduce the false alarms and to save ambulance resources for the mostly critical patients and avoid ambulance misuse, for the “general and stable” cases, instead of utilizing EMS ambulance, other designated mobile units including the caregiver, the neighborhood volunteers, or the other community first responders such as guards running by bike, feet, or motorbike would visit the target elderly first and then arrange the proper transport if they really need to seek the hospital care (Lin et al. 2015; <http://www.pulsepoint.org/pulsepoint-respond/>; <https://www.pulsepoint.org/pulsepoint-respond/>).

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 6 Triggering of corresponding EMS managements at the NIS controller

Neighborhood-Based ICT-Driven Support (NIS) System of Emergency Medical Services (EMS) for Elderly People in Hyper-Aged Societies, Fig. 7 Triggering of corresponding EMS managements to the caregiver elderly people

scdf.gov.sg/content/scdf_internet/en/community-and-volunteers/mobile_phone_technology.html).

Figure 7 illustrates the model of triggering the corresponding EMS managements specific to the caregiver elderly people at NIS master node. The details are described as follows:

- Step 1. When the caregiver elderly people have a problem, the abnormal situation may not be well known because of its server node and caregiver character not being cared as client node by other elderlies.
- Step 2. The dispatch center may actively activate the robot remote control to make it access the caregiver.

- Step 3. In NIS server node, the robot remote control could access caregiver’s situation through voice, video, or motion detection functions to get the situation category.
- Step 4. The remote and automatic assessments by robot of caregiver’s situation would be transmitted back to the dispatch center to gather better information for prompt EMS response.
- Step 5. The designated rapid response volunteers for assistance to caregiver would be soon activated to NIS server node to check caregiver’s condition and to provide helps. Before their arrival if the robot assessments showed urgent or critical status, the EMS ambulance would

be sent out concurrently with the rapid volunteer response (Lin et al. 2015; <http://www.pulsepoint.org/pulsepoint-respond/>; https://www.scdf.gov.sg/content/scdf_internet/en/community-and-volunteers/mobile_phone_technology.html).

Network Coding-Aware Routing in Wireless Ad Hoc Networks

[Network coding](#); [Network coding-aware routing](#)

Definition

Network coding-aware wireless routing is a routing paradigm that takes into account network coding gains and broadcast benefit at wireless nodes in route selection for supporting efficient data delivery in wireless networks to improve the network performance.

Historical Background

Coding-aware routing protocols can be classified into two categories: centralized protocols and distributed protocols.

Centralized protocols depend on centralized linear programming formulations in which a central controller is responsible for making the routing decisions for all requests by using global state information. Some typical work in this aspect is as follows. Sengupta et al. (2007) proposed a linear-programming-based interflow coding-aware routing protocol. The authors derived a theoretical formulation for computing the network throughput on any wireless topology with any pattern of concurrent unicast sessions by making routing decisions with the awareness of potential network coding opportunities at different nodes. Ni et al. (2006) proposed a coding-aware routing protocol using linear programming to improve the network performance by reducing the expected number of coded transmissions for successful exchange of packets via interflow network coding. Although these centralized coding-aware routing protocols can improve the network performance in terms of resource utilization and throughput, their centralized characteristic leads to the scalability problem. Moreover, centralized protocols have the issue of single point of failure and the central controller could be a bottleneck of the whole network. Therefore, they are not suitable for being employed in dynamic multihop wireless ad hoc networks.

In distributed coding-aware routing protocols, nodes in the network independently make localized routing decisions based on the network state information each of them locally collects/maintains. In the literature, there are two types of distributed protocols: source routing protocols and hop-by-hop routing protocols. In source routing, the source node of a flow locally computes an end-to-end path from the source node to the destination node with more coding gains by using certain global state information (including global network topology, state information of each link in the network, and paths taken by other communication

requests). In hop-by-hop routing, each routing decision is made based only on the limited local state information that the packet holder collects/maintains. As the result, hop-by-hop routing has low complexity/overhead and is thus suitable for being deployed in dynamic wireless ad hoc networks. In recent years, several hop-by-hop coding-aware routing protocols have been proposed. In Wu et al. (2007), to support efficient interflow network coding, Wu et al. designed a Markovian routing metric, which is defined as the cost of sending a packet across a link and its value depends on the link where the packet comes from. This metric can work with an existing routing protocol to choose paths with more network-coding opportunities. Le et al. (2008) proposed an on-demand distributed coding-aware unicast routing protocol (DCAR) for selecting routes with more potential coding gains to improve the network throughput by introducing a coding-aware routing metric that jointly considers potential coding opportunities, congestion levels, and other related factors. Yan et al. (2008) designed a rate-adaptive coding-aware multiple path routing protocol (RCR) for wireless multihop networks. The main design objective is to improve the network performance via traffic splitting for maximizing the coding opportunities in the wireless networks. Yan et al. (2016) considered the interplay between transmit power, transmit rate, and network coding gain in a wireless ad hoc network and they proposed a distributed network coding aware power/rate control protocol, which allow each node to adaptively adjust its transmit power and data rate such that spatial-temporal bandwidth resource in the network is fully utilized via using efficient coding-aware transmissions, whenever applicable. All the above four protocols were designed based on the traditional best-path routing protocol, and none of them considered impact of the lossy characteristic of wireless channel on the efficiency of coded packet transmissions. To respect such impact, CORE (Yan et al. 2010) is designed to improve the link-level data delivery reliability and network throughput and it combines hop-by-hop opportunistic forwarding and localized

interflow network coding by exploiting the lossy characteristic of wireless channel. A common feature of all the above five protocols is that they focus on interflow network coding-based routing for improved network performance. Some other work (e.g., Chung et al. 2012; Seferoglu et al. 2011; Khreishah et al. 2013) had also considered hybrid approaches that exploit both interflow network coding and intraflow network coding for lossy wireless ad hoc networks where interflow network coding considers encoding packets from different flows and intraflow network coding considers encoding packets from the same flow.

Foundations

Recently, wireless network coding has been proposed as an effective paradigm to achieve high throughput performance of wireless ad hoc networks. Wireless network coding can obtain network coding gains from the inherent broadcast nature of wireless medium in the wireless networks by mixing multiple packets in a single transmission. Figure 1 illustrates the basic idea of network coding in a wireless network, which was first reported in Sengupta et al. (2007). In Fig. 1, node X and node Y want to exchange packets via a common intermediate node R , X sends packet pkt_1 to Y and Y sends packet pkt_2 to X . After node R receives both packets pkt_1 and pkt_2 , it can create a new xor-coded packet " $pkt_1 \text{ xor } pkt_2$ " and then broadcast it to the air. Upon the receipt of the coded packet, both X and Y can decode their

Network Coding-Aware Routing in Wireless Ad Hoc Networks, Fig. 1 A simple example illustrating how wireless coding improves the throughput of wireless networks. (a) No coding and (b) coding

interested packet by using the packet received and the packet information that it locally stores. The number of total transmissions in this example is thus reduced from four to three.

With the assistance of wireless network coding, coding-aware routing protocols combine localized network coding and route selection to significantly improve the network throughput performance and also reduce the number of transmissions in wireless networks. The objective of coding-aware routing is to enable efficient communications in wireless networks by reducing the number of packet transmissions by utilizing network coding opportunities and also improve the network performance such as network throughput, packet delivery delay, etc. Therefore, implementation of coding aware routing in wireless networks requires to consider both network coding gains and routing cost (e.g., delay, throughput, and packet loss) in traditional routing protocols, in order to achieve improved network performance effectively.

The basic idea behind coding-aware routing can be illustrated by the following example. Consider the example network in Fig. 2. Suppose there are two flows: one from node *A* to node *E* and the other from node *F* to node *A*, and further suppose there exist no loss over wireless links. The traditional shortest paths for these two flows are $A \rightarrow B \rightarrow C \rightarrow E$ and $F \rightarrow D \rightarrow B \rightarrow A$,

respectively. In this case, we can see that there exists no coding opportunity if both *A* and *F* decide to forward packet along their corresponding shortest paths. However, if *F* can forward its packets via *E* to *A*, then the path from *F* to *A* will be detoured onto $F \rightarrow E \rightarrow C \rightarrow B \rightarrow A$. Although this path has one more extra hop than the corresponding shortest path, it creates coding opportunities at nodes *C* and *B*. The total number of packet transmissions in this case will be reduced by the coding-aware forwarding strategy. The network throughput can also be improved as a result.

Key Applications

Network coding-aware wireless routing is beneficial in wireless multihop networks where network coding opportunities exist and efficient wireless routing is required to improve the network resource utilization efficiency.

Definitions

Network effect has been defined as the value or surplus that an agent derives from the goods/service when the number of other agents consuming the same kind of goods/service changes, which could be positive or negative.

Historical Background

Network economics, inherently, is an interdisciplinary research area between economics and networks. Economics is the social science that analyzes the production, distribution, and consumption of goods and services. As for networks, the focus is on connectivity, which could be referred to as market network with many network industries, social networks that permeate our society and daily life, or the communication networks (e.g., Internet) in engineering area. Equipped with economic theory, the economic features of networks can be analyzed. Undoubtedly, network modeling and analysis in economics is more than a fad. The ubiquity of networked interactions in economic settings clearly shows that network economics analysis should continue to grow rapidly (Bramoulle et al. 2016).

There is a fundamental property of networks, i.e., the fact that they exhibit network externalities due to complementarity of network structure (Economides 1996). The seemingly simple phenomenon has brought a great influence to the majority of networking progress, including network formulation, network competition or coalition, and network segmentation, hence to a large extent determines market strategies and outcomes in network markets. Considering the value of one node without looking into its activity in the network or without incorporating the role it can play in growing the network due to network externality is myopic. Therefore as the core issue of network economics, the study for network externality is highly significant and necessary for providing a guide toward understanding the network itself. Besides, network resource allocation policies are a major issue of networking progress, while pricing is a powerful countermeasure for allocation issues in most times, which inevitably demands our attention.

Network externality has been defined as the surplus that an agent derives from the service when the number of other agents consuming the same kind of service changes, which could be positive or negative (Shapiro and Varian 2013; Liebowitz and Margolis 1994; Katz and

Shapiro 1985; Liebowitz and Margolis 1998; Farrell and Saloner 1985). Fax machine and telephones are two obvious positive examples, which become increasingly valuable and hence more attractive to one user if there are more users adopting it, similar to Facebook and Twitter in social networks. Strictly speaking, *network effects* should not properly be called *network externalities*. Unfortunately, the term externality has been used somewhat carelessly in many economic literatures which cause some ambiguity.

Early literatures denote the network effects and network externalities as the same, with the meaning or description when the value of a product to one user depends on the total number of adopters (for discussion see (Katz and Shapiro 1985; Shapiro and Varian 2013)). Another portion of literature denotes the network externalities are caused by network effects. Specifically, *network externalities* refer to the economic concept of the externalities entailed in network effects. When the owner of a network or participants is able to internalize such network effects, they are no longer externalities (Liebowitz and Margolis 1998, 1994). Recently, some papers define network effects as one special case of positive network externalities; also they extend the meaning of network externality (Huang and Gao 2013), which is more realistic. In their definition, network externalities reflect the situation where each user's utility is affected by other users' decisions. After all, any economic effect is an externality if not internalized since the externality is more general (Farrell and Klemperer 2007). But it has not been adopted by many scholars.

Putting aside definitional concerns, this chapter merely focuses on considering and discussing the extra value owing to the network effects and gives a relative comprehensive review on the topic from different perspective. *Network effects* are implied as positive in most times. For brief, this chapter uses the term "*network effects*" to replace positive network effects in subsequent discussion. Furthermore, this chapter follows the most economic literature's idea and predefines *network effects* as the phenomenon when a good or service becomes more valuable when more

people use it, which is denoted as positive network externality (Shapiro and Varian 2013). The chapter may use these two terms interchangeably for the same meaning.

The "*network effect*" is often highlighted in social and economic viewpoints (Tucker 2008); however until recently, network effects have been discussed and applied in communication networks. As for data communication networks, many papers simply assume the network effects are not dominant like congestion or interference effects hence easily ignored without discussion. They obviously leave out some situations with the presence of significant network effects, where the attention should be paid enough, which is exactly the motivation for the chapter. For example, the authors in Blackburn et al. (2013) studied the users' calling behaviors concerning the usage of cellular service such as data, SMS message, and voice calls, which affects economics of cellular provider with the analysis of real telecommunication service data. Furthermore, the real data is leveraged to validate the existence of underlying network effects. Additionally, the authors in Blackburn et al. (2013) provides the pioneering motivation for planning and developing the pricing mechanisms for future work. As one of the key issues of network economics (Chiu and Ng 2011), network effects exist in many connected communication network platforms such as Internet, mobile, and ad hoc network and peer-to-peer communication networks (Easley and Kleinberg 2010).

Preliminaries of Pricing Network Effects

This section briefly introduces and describes basic definitions in network economics, strengths or weakness, and mathematical models that can be referred to later in the sequel.

Definitions and Interpretation

Network externalities can be either positive or negative. The negative network ones have been extensively investigated in many existing research works (Shy 2011; Chiu and Ng

2011), such as the congestion and interference in wired and wireless networks in Gibbens et al. (2000) and MacKie-Mason and Varian (1995), respectively. However, as for positive externalities or network effects, there are a limited number of literatures especially on communications. This chapter does not focus our attention on negative externalities in this chapter, yet the situation – positive network externalities appear together with negative ones – is considered, which was investigated probably for the first time in Chao (1996) and mainly takes place in communication networks (Johari and Kumar 2010; Gong et al. 2015; Zhang et al. 2016a, 2017a).

In the literature, the network effects are mainly categorized into three types. Direct network effects or same-side network effects have been defined as those generated through a direct physical effect of the number of consumptions on the value of service or good. For example, in peer-to-peer communication networks, more users increase the value of the network by giving more destination options. Indirect network effects are usually the cases where complementary goods provider gains more value as the number of users of a good increases. When the interaction is reciprocal, this chapter calls it two-sided network effects and cross-side or cross-group network effects, which are a special case of indirect network effects (Rochet and Tirole 2006). Again take the peer-to-peer communication networks, for example, the more existing users enable the peering network to function at lower cost and higher capacity as well as service quality, which in turn benefit the users themselves.

Local (peer-to-peer) network effects or social network effects consider the localized effects of users rather than the global network effects (direct or indirect), where each user is influenced directly by the decisions of only a typically small subset of other users (Sundararajan 2005, 2007). For example, Zune players can share music with people around, so the utility obtained by a Zune player directly depends on the number of its friends sharing the music on Zune. Another more direct and relevant case is instant messaging, the utility of one user is critically determined

by the number of its friends who use the same instant messenger. Generally speaking, the local network effects mainly focus on the structure of an underlying social network.

Benefits and Problems

As discussed in the last section, the pricing mechanism is mainly used for revenue maximization by service or goods providers as a methodology of allocation policies, which are conducive to appeal to users. The growth of the adopter base is represented as one of the most significant metrics to reflect success. Generally speaking, traditional price increases with quantity demanded of the service or products due to economic equilibrium; hence the usage-based pricing is frequently used in network services. However due to the presence of network effects, another important consideration – size of network – which has a direct relation with the value obtained by users requires our attention. In Fig. 1, assume the cost is fixed for selling the service/products in a market network; the total cost of all users is denoted as a straight line with the increase of consumers/users. Due to network effects the real value of service/products is represented as a sigmoidal curve, which has three cross-points (market equilibria) with former straight line, the middle equilibrium is not stable because any change regarding market size causes the network to converge to one of another two equilibria.

Network Effects, Fig. 1 Market equilibria with network effects

The similar observation comes from many other studies involving network effect (Chiu and Ng 2011).

From another specific perspective in Fig. 2, it is intuitively observed that there are more details on external benefits for the sake of network effects. Here external benefits are denoted as difference of social value and private value. The social benefit (or revenue) includes not only the consumers' own benefits of getting the service/products (marginal benefits) but also the external benefits. Thus, the social marginal revenue is larger than the private marginal revenue, as shown in Fig. 2. Each of value curves has an intersection with supply (private costs) curve, which denotes the corresponding equilibrium.

Moreover, the optimum demand from social level is Q_{eff} that denotes the efficient equilibria in terms of quantity, which is larger than the normal market demand Q_{mkt} from the level of private profit maximization. When a product has external benefits due to network effects, the market equilibrium is lower and there remains underused resources that cause deadweight loss (shadow areas), so how does the provider handle the situations? Obviously, the corresponding pricing strategies should be designed with the consideration of extra benefits caused by network effects. Intuitively, the provider should take measures to shift up the demand (private value) curve and then achieve the higher efficient equilibrium. One common solution is Pigouvian subsidy which

Network Effects, Fig. 2 Problems (market failures) without taking into consideration of network effects

encourages people to consume while guarantees that private value plus subsidy equals to social value. Generally, the network effect plays an important role in improving the performance of a pricing strategy.

Application Scenario in Wireless Networks with Network Effects

The pricing schemes are designed to offer profitable business to the service providers, as well as to create favorable services for the users, which is a useful tool for allocation issues (Huang and Gao 2013). Since users typically share limited resources in data communication networks, congestion effect from physical domain on users' behavior is common and has been extensively investigated for pricing strategies by many works (MacKie-Mason and Varian 1995; Blumrosen and Dobzinski 2007; Sengupta and Chatterjee 2009; Hande et al. 2010). For example, if an Internet service provider becomes oversubscribed, its subscribers suffer from the congestion externality due to limited bandwidth and radio resources. However, very few works of network effects take homophily phenomenon into consideration, i.e., network effects. The social aspect of mobile networking is an emerging paradigm for network design and optimization (Gong et al. 2017b). In Brown and Reingen (1987), the authors found that the information obtained from social tie connections will influence in decision-making. Inspired by Brown and Reingen (1987), the social group utility maximization framework was proposed in Gong et al. (2017a) and Chen et al. (2016), which captures the impact of users' diverse social ties that are subject to diverse social relationships. The authors in Blackburn et al. (2013) showed the evidence of network effect in communication service using the real data analytic and quantified such effect using a simple metric. The finding of Blackburn et al. (2013) provides the motivation for planning pricing mechanisms with network effect in the real markets.

Recently, the network effect has been considered jointly with service pricing from the economic perspective. For example, in the pioneering work (Candogan et al. 2012), the authors investigated both the uniform pricing and the discriminatory pricing of the service provider in the presence of network effects. In Makhdoumi et al. (2017) and Swapna et al. (2012), the authors discussed the dynamic pricing strategy of divisible social goods with network effects. However, the authors investigated the user behaviors only in social networks without considering the congestion in wireless network. Therefore, the model introduced in Makhdoumi et al. (2017) has a major limitation as it cannot be applied into the wireless network environment, in which the radio resource is scarce and congestion can frequently happen. Subsequently, the authors in Gong et al. (2017b) formulated the interaction between a wireless service provider and mobile users as a two-stage Stackelberg game, based on the model presented in Candogan et al. (2012). In the upper Stage I of the formulated game, the service provider acting as the leader determines the price for users. Then, the users acting as the followers simultaneously decide on the data usage level maximizing their individual utilities given the price in the lower Stage II. The uniform pricing scheme was adopted, where the impacts of network effects and congestion were jointly analyzed. In Zhang et al. (2016b, 2017a), the authors studied the similar problem to that in Gong et al. (2017b), where the discriminatory pricing strategy was applied by the provider. The authors in Zhang et al. (2016a) further investigated a market where multiple wireless service providers exist and focused on the competition among the providers. In Xiong et al. (2017b), the authors studied the sequential dynamic pricing scheme where the user's behavior are subject to both the network effects and congestion effects. Specifically, the provider can utilize its ability to modify its strategy in response to the observed history. Similarly, the authors in Zhang et al. (2017b) analyzed the impacts of network effects on cloud computing resource allocation. The authors in Nie et al. (2017) exploited the network effects to design the incentive mecha-

nism for engaging more participants in the mobile crowdsensing platform.

Another socially aware communication network is the sponsored content. Sponsored content enables a content provider to pay a wireless network service provider (SP), and thereby mobile users can access contents from the content provider (CP) through network services from the service provider with lower charge. Thus, more users want to access the contents which potentially generate more profit gain to the content provider. The authors in Wang et al. (2017) focused on the service-selection process among the mobile users as an evolutionary population game and demonstrated how global network effects and sponsoring helps improve the SP's revenue and the mobile user's experience. The authors in Xiong et al. (2017a) conducted economic analysis on sponsored content in the presence of social network effects, where the interactions among the SP, CP, and MUs are modeled as a three-stage game. Under the similar model, the authors in Xiong et al. (2018b) further investigated the sequential competition and cooperation between the CP and SP. Lately, the authors in Xiong et al. (2018a, submitted) proposed a joint sponsored and edge caching content model under noncooperative game framework, where the mobile users can access sponsored content using 4G link and edge caching content via Wi-Fi link. Therein, the mutual interplay between the edge caching CP and sponsored CP is the main concern.

Conclusions

"Network effects" is an interesting phenomenon whereby "more connected users and more benefits," which originally comes from network economics. At the same time, pricing has been widely investigated for service or product's provider in terms of revenue maximization all this time. This chapter focuses on the "network effects"-based pricing from analytical and practical perspective. The work lies in the area of pricing as well as revenue maximization in the presence of network effects, with an emphasis

on communication services. Meanwhile, this chapter has implemented with the tutorial parts with respect to basic definitions and models on pricing and network effects. Furthermore, this chapter has presented several actual application scenarios on pricing network effects. The hope of this chapter is that the novel insights from economic and sociological viewpoints will be helpful to researchers from telecommunication's area regarding pricing of emerging socially aware service with network effects and enable the engineers to apply the economic strategies from one subject to another. Many questions remain open and may be ripe for subsequent theoretical and even practical investigations in the next few years.

Key Applications

Mobile or wireless social networks where the network effects and congestion effects both exist, or some emerging communication applications such as crowdsensing, user provided network, and sponsored content platform.

Definitions

Network information theory is the extension of the classical information theory for point-to-point communications to networks of nodes exchanging information.

Historical Background

In 1948, Claude Shannon, the father of information theory, published his revolutionary paper “A Mathematical Theory of Communication” (Shannon 1948). In the paper, the most significant result is arguably given by the channel coding theorem, which answers one of the most fundamental questions in information theory, namely,

what is the ultimate transmission rate of communication. Roughly speaking, the channel coding theorem says that there always exists a maximum achievable rate for a channel, called the channel capacity, below which the reliable communication can be implemented while above which the reliable communication is impossible.

While Shannon's classical information theory addresses point-to-point channels and has had profound impact on modern communication systems, network information theory (El Gamal and Kim 2011) considers communication networks containing multiple senders and receivers, e.g., computer networks and satellite networks, and its main goal is to find the fundamental limits in network communications and the optimal coding schemes to achieve these limits. The presence of multiple senders and receivers in the network settings brings in many new elements to the communication problem, such as interference, cooperation, and feedback, but also makes the problems difficult to solve. To date, there is as yet no unified theory of network information flow, although such a complete theory is expected to have wide implications for today's communication networks, especially the currently ubiquitous wireless communication networks.

Problems in Network Information Theory

Given that the solution to the general problem is out of reach, various special problems in network information theory have been studied extensively over the past few decades, including distributed source coding, multiple-access channel, broadcast channel, interference channel, relay channel, etc. In distributed source coding, multiple (two or more) sources are separately encoded at their corresponding rates, and the descriptions are communicated over noiseless links to a decoder who wishes to recover all the sources either losslessly or within some distortion; the problem is to determine the set of simultaneously achievable description rate vectors, i.e., the rate vectors at which the sources can be recovered in a lossless or lossy sense. While distributed source

coding remains an open problem in general, it has been solved in the lossless case, and the achievable scheme is now known as Slepian-Wolf coding (Slepian and Wolf 1973). In a multiple-access channel, multiple senders send information to a common receiver, and the problem is to determine the capacity region, i.e., the set of rate vectors at which the senders can reliably communicate to the receiver simultaneously. The multiple-access channel has been completely solved, and one can achieve its capacity either by successive cancellation decoding or by simultaneous decoding (Ahlsweide 1973). The broadcast channel describes the scenario where there is one sender and multiple receivers. While the capacity region for general broadcast channels is still unknown, it has been determined for some special classes, for example, the degraded broadcast channels where the capacity is achieved by superposition coding (Cover 1972). The interference channel (in the simplest setting) has two senders and two receivers, with the signals of the two senders interfering with each other. The capacity region of the interference channel is not known in general except for several special cases such as the strong interference case (Sato 1981); a prominent achievable scheme for the interference channel is the Han-Kobayashi coding scheme which employs rate splitting and superposition coding (Han and Kobayashi 1981). The relay channel models a communication scenario where there is a relay node that can help the information transmission between the source and destination. While the capacity of the relay channel is generally unknown, substantial advances have been made in Cover and Gamal (1979), where a general upper bound on the capacity, now known as the cutset bound, together with two fundamental relay schemes, namely, decode-forward and compress-forward, is developed.

Recent Progress

Motivated by the increasing development of wireless networks, the past decade has witnessed significant progress in network information theory, on both the achievability and converse

sides. On the achievability side, a plethora of new coding schemes have been developed for network problems, ranging from the extension and unification of decode-forward and compress-forward to the case of multiple relays (Xie and Kumar 2005; Kramer et al. 2005; Lim et al. 2011; Wu and Xie 2013, 2014), to schemes based on interference alignment (Cadambe and Jafar 2008) and distributed MIMO (Ozgur et al. 2007), to lattice-based techniques (Nazer and Gastpar 2011), and to strategies inspired by network coding and linear deterministic models (Ahlsvede et al. 2000; Avestimehr et al. 2011). On the converse side, proof techniques that build on geometric and functional analysis have been introduced very recently, which lead to the solutions of several long-standing open problems in the field. For example, an open question regarding the capacity of the relay channel has been solved via a geometric approach in Wu et al. (2016), and the “missing corner point” in interference channel has been settled by using transportation-information inequalities in Polyanskiy and Wu (2016).

[Cooperative MIMO](#); [Virtual MIMO](#)

Definition

Network MIMO is a family of cooperative multiantenna transmission/reception techniques for wireless communications. With network MIMO, multiple wireless access points share user data and channel state information via high-capacity backhaul links and perform joint precoding to transmit to multiple user devices in the downlink and jointly decode the received signals for different users in the uplink.

Historical Background

Point-to-point multiantenna transmission and reception techniques, known as *single-user MIMO*, were developed in 1990s to support high-speed wireless communications. Being able to greatly increase throughput via utilizing spatial domain resources without bandwidth expansion, they formed key enablers for broadband wireless communications systems, including wireless local area networks (IEEE 802.11n and IEEE 802.11ac) and cellular networks (WiMAX and LTE). The great success of MIMO drove efforts to further exploit its potential, and various theoretical studies and practical signal processing techniques were then developed for *multiuser MIMO* systems. Since 2001, the concept of *network MIMO* arose, mainly in the form of base station cooperation in cellular networks. It was proposed to reap the technical maturity of traditional MIMO techniques and also to overcome the fundamental limitation in cellular networks, i.e., the intercell interference caused by co-channel communications in multiple cells.

By sharing user data and channel state information among multiple nodes, network MIMO transforms an interference limited system into a virtual multiuser MIMO system. Initial studies investigated the application of various multiuser MIMO processing techniques in the network MIMO setting. For example, Shamai and Zaidel (2001) applied dirty paper coding for base station cooperation in the downlink, which

is the optimal scheme for multiuser MIMO. In Zhang and Dai (2004), both dirty paper coding approach and several practical joint transmission schemes were investigated for downlink base station cooperation, with a per base station power constraint.

The performance gains of network MIMO techniques, especially their ability to mitigate intercell interference, attracted great attention from the industry. Bell Labs, which demonstrated the first MIMO system, also pioneered in the investigation on network MIMO. In a series of papers (Foschini et al. 2005, 2006; Venkatesan et al. 2007), they confirmed that network MIMO is capable to significantly increase throughput under realistic propagation and operational conditions. In particular, the name of *network MIMO* first appeared in Venkatesan et al. (2007).

Around 2008, as the LTE standard was close to completion, the importance of interference management in the new LTE network was well recognized. Various interference coordination and cooperation techniques were tested, and simple coordination schemes were included in the LTE standard, e.g., fractional frequency reuse (FFR) was supported by LTE Release 8, and enhanced intercell interference coordination (eICIC) was supported by LTE Release 10. To further enhance the performance, a work item on coordinated multipoint (CoMP) transmission/reception was formed in 3GPP LTE-Advanced, which unified several network MIMO techniques. In 2011, CoMP was included as a key feature in LTE Release 11 (Irmer et al. 2011).

Foundations

Network MIMO builds upon traditional MIMO techniques, including single-user MIMO and multiuser MIMO, and it can overcome their limitations. It can effectively mitigate intercell interference and thus is attractive for cellular networks.

By deploying multiple antennas at the communication nodes, MIMO techniques can effectively

increase the capacity of wireless communications systems via spatial signal processing, without bandwidth expansion. The capacity of a single-user MIMO system grows linearly with the minimum number of transmit and receive antennas. Due to the space limitation, however, each mobile device can only have a small number of antennas, normally one or two, which thus bounds its capacity gain. Multiuser MIMO, where a base station communicates with multiple mobile users simultaneously, provides an opportunity to boost the total throughput even with single-antenna users. Nevertheless, for multiuser MIMO serving a large number of users, the sum capacity is restricted by the number of antennas at each base station. By cooperating multiple base stations, network MIMO essentially creates a giant virtual base station, and thus, it can increase the available spatial resources and overcome the limitation of multiuser MIMO.

Another difficulty in deploying traditional MIMO techniques in practical systems is the effect of intercell interference. The cellular network by design is interference-limited, and the transmission in each cell acts as interference to other cells. The situation gets worse as universal frequency reuse is advocated in modern wireless networks. While the problem of intercell interference is inherent to cellular systems, its effect on MIMO is more prominent as each neighboring base station antenna element acts as a unique interfering source, thereby making it difficult for the mobile user to estimate and suppress them. Studies (Catreux et al. 2000; Blum 2003) have shown that the capacity gains promised by MIMO techniques are degraded severely in the multicell environment. Different from conventional methods to suppress intercell interference, network MIMO attacks this problem from a fundamentally different perspective. With joint processing among multiple base stations, network MIMO turns otherwise harmful interference into useful signals, i.e., it eliminates intercell interference. This is especially important for cell edge users, who previously suffer from severe intercell interference and now can get a performance boost by receiving

from/transmitting to multiple cooperative base stations.

Network MIMO techniques are attractive due to their significant performance gains. Their practical implementation, however, faces several key challenges, including the complexity of the cooperative processing, the requirement of a high-capacity backhaul network, the high signaling overhead, and channel state information (CSI) acquisition. Joint processing among base stations significantly increases the computational complexity. Network MIMO requires data sharing among multiple base stations, which calls for high-capacity backhaul links and significantly increases the signaling overhead. In order to support joint processing, CSI of all the users to all the cooperating base stations is needed, which causes significant training and feedback overhead. Great efforts have been spent to address these issues, and following are some potential techniques and solutions.

- *Low-complexity joint precoding and decoding:* To reduce the computational complexity of joint processing in network MIMO, linear schemes are preferred, e.g., zero-forcing precoding (Huh et al. 2012; Zhang 2010). Such schemes have been developed for multiuser MIMO, and they can be modified for network MIMO systems. One major difference is that per base station power constraint should be considered. Another approach to reduce complexity is via decentralized precoding, which allows each base station to locally process its received signal (Ho et al. 2011).
- *Clustered cooperation:* Clustering is an effective means to reduce the processing complexity, the amount of data sharing between base stations, as well as the required CSI. Base stations within each cluster can eliminate intracluster interference among users via joint precoding/decoding, which only requires local data and CSI sharing within the cluster. To improve the cluster edge performance, limited intercluster coordination methods can be applied to suppress interference for cluster edge users (Zhang et al. 2009).

- *Finite-capacity backhaul*: Theoretical performance gains of network MIMO are obtained by assuming high-capacity backhaul links. In practice, backhaul links are with finite capacity, which will affect the achievable data rate. One method to improve the performance with finite-capacity backhaul links is to adapt the cooperation scheme based on channel realization (Marsch and Fettweis 2008). Novel compression techniques should also be developed to deal with limited backhaul capacity, e.g., via joint signal and CSI compression (Kang et al. 2014).
- *CSI acquisition*: Accurate CSI of each user to all the cooperating base stations plays a critical role in network MIMO. Taking downlink transmission as an example, such information can be obtained via downlink training and uplink feedback. For downlink training, it is important to determine the amount of pilot symbols needed, which depends not only on the network size, but also on the backhaul capacity (Hoydis et al. 2011). To feedback estimated CSI to the base stations, each user can apply adaptive limited feedback to improve the performance with a given feedback bit budget, which partitions the available feedback bits between the desired and interfering channels (Bhagavatula and Heath 2011).

Key Applications

Network MIMO can be applied in wireless networks where distributed access points are connected via high-capacity backhaul links. It helps to suppress interference and improve the network throughput, as well as cell edge throughput.

[Network privacy supervision and privacy preserving](#)

Definitions

Network privacy surveillance and protection issues include the protection of individual sensitive information in collection, storage, analysis processes and their application for administration and economic interest. It is also concerned with the balance between privacy protection and usability.

Historical Backgrounds

Privacy surveillance and protection are fundamental topics arising to be our increasing concerns in the era of the Internet (Lyon and Zureik 1996; Ashrafi and Kuilboer 2018). The governments in many countries have started to collect individual private information from public administration purpose even before such information was regarded as private (Warren and Brandeis 1890). With new legislation efforts government is gaining more control over private life of public (Parliament of Canada 2003; Young 2010; Meece 2012). In addition, new

technologies such as Cloud Computation, Big Data, Mobile Internet and Internet of Things, even though they have benefited our daily life magically, enable governments and corporations to monitor public technically. Similarly, Video surveillance cameras, biometrics, domestic drones, face recognition technology, RFID chips, and stingray tracking devices also become the basic privacy collecting and surveillance technologies (American Civil Liberties Union 2013), facilitating governments and corporations in the collection of more and more private information, and storage and application in of those information for administration and economics reasons. Privacy becomes prone to be abused, resulting in violation of individual rights, informational inequality, informational injustice and discrimination, and encroachment on moral autonomy. Therefore, it is extremely important to protect privacy, find appropriate balance between information utilization and privacy protection.

Privacy Definition and Identification Technology

As privacy is closely related to individual preferences, independence and the entire society, it's not easy to define privacy precisely. The professor of law (Westin 2003) believes that privacy is something focusing on *individuals*. This understanding is considered too broad to define privacy accurately. But from the perspective of the application, privacy is mostly depended on the characteristics of the application scenario. According to the difference of service objects, privacy definitions can be varies based on user's identity on user's identity or user data (Bordenabe 2014). The former concerns with privacy leaks in link attack to recognize user identities, such as the property in *k*-anonymity, *l*-diversity; for the latter, the detailed data is regarded as protection object, and it assumes that the adversary has known the user's identity, such as differential privacy.

Traditionally, privacy is identified based on prior experience. Now, it can be based on privacy features which are produced in different application scenarios (Xu et al. 2015).

For example, biometrics obtained from video data with highly discriminatory and uniqueness can be used as the direct conduit between the identity and data, essentially the identification of privacy (Luo et al. 2018). Moreover, with the development of machine learning, privacy can be learnt from cumulative data. These technologies can be roughly divided into two categories, one (Bordenabe 2014) is to set a trusted learner that has permission to access private database, but the way relies on the exponential mechanism. The other includes a group optimal composition chosen from the findings to user regarded as training set, and algorithms based on EM or SVM to identify privacy, even hierarchical classification.

Laws and Policies

There are three typical modes of personal information protection in the world: EU Legislative Mode, American Protection Mode, and Japanese Protection Mode. In the EU Legislative Mode, personal information is regarded as a part of individual personality and human rights. In 1995, the publication of the EU *Data Protection Directive* established the basic principles for personal information protection. In 2009, Britain issued the first personal information protection standard BS10012 *Specification for a Personal Information Management System* Young (2010). Additionally, the *General Data Protection Regulation (GDPR)* (EU) 2016/679 (European Parliament 2018b) becomes the most important law on data protection and privacy for all individuals in the European Union. American Protection Mode is based on the right to privacy. It is a combination of decentralized legislation and industry self-discipline. The *Privacy Act* (The 93th United States Congress 2018) passed in 1974 is the basic law to protect personal information privacy in the USA. Subsequently, the *Sunshine Act* (The 94th United States Congress 1976), the *E-Government Act* (The 107th United States Congress 2016), and *Consumer Privacy Bill of Right* (Meece 2012) were passed to protect personal information from different industries. Japanese Protection Mode also combines govern-

ment legislation and industry self-discipline. In 2005, in Japan the *Personal Information Protection Act* (Parliament of Canada 2003). Combined with the *Personal Information Protection Ordinance* formulated by local governments, Japan has built a relatively complete legal system for personal information protection.

Privacy Protection Technologies

Anonymous

Regarding the privacy leakage caused by linking attack in dataset publishing, in 2002, Sweeney (2002b) proposed an anonymity model. Through the suppression and generalization (Sweeney 2002a) techniques, indistinguishability between the quasi-identity attributes is achieved. However, the existence of k -anonymity cannot resist homogeneity attack and background knowledge attack. Machanavajjhala et al. (Machanavajjhala et al. 2007) proposed l -diversity, constrained publishing data sheets, k -anonymity group sensitive attribute values to satisfy l diversification. However, the fact that l -diversity cannot resist the homogeneous attack and similarity attack, researchers have proposed an anonymous privacy protection model of t -closeness (Li et al. 2007). At present, the anonymous model has been applied in various fields including social network privacy protection, trajectory privacy protection and so on. Meanwhile, a large number of researchers extend k -anonymity to face different attacks. We will briefly summarize anonymous models and applications in Fig. 1.

Differential Privacy

Differential privacy is one of the most famous privacy notions which offer a rigorous and provable privacy guarantee for *Privacy Preserving Data Mining (PPDM)* and *Privacy Preserving Data Releasing (PPDR)* (Zhu et al. 2015). The motivation of differential privacy is to allow statistical analysis of the dataset without disclosing individual information. A formal definition is as follows (Dwork 2006, 2008; Dwork et al. 2006):

Network Privacy Surveillance and Privacy Protection, Fig. 1 Anonymous models and applications

Definition 1 A random mechanism M offers ϵ -differential privacy for any pair of D and D' , denoted as $D \sim D'$, and for every set of outcome space O , the ratio of output probabilities satisfies Eq. 1:

$$\frac{Pr[M(D) \in O]}{Pr[M(D') \in O]} \leq \exp(\epsilon) \quad (1)$$

Privacy budget ϵ determines the effect of privacy protection. The smaller the parameter ϵ is, the more noise. As such, an appropriate ϵ is the key to tradeoff accuracy and privacy. There are two basic methods to achieve differential privacy, namely *Laplace Mechanism* and *Exponential Mechanism*. But no matter which one is chosen, the global sensitivity is used to calibrate noise. For a query $Q : D \rightarrow R^k$, the *Global Sensitivity* is defined as

$$GS = \max_{D, D'} \|Q(D) - Q(D')\|_1 \quad (2)$$

Differential privacy can be classified into two categories: interactive and non-interactive. In a non-interactive setting the curator publishes a sanitized version of original dataset in order to protect individual information. While in the

interactive setting, trusted data curator receives queries from the analyst, adopts differential privacy mechanism and answers the queries with adaptive selection of noise distribute (e.g. Laplace distribute, Exponential distribution). Here, we use Fig. 2 to illustrate these differential privacy interactive settings.

Cryptographic Technologies

Cryptography plays an important role in privacy protection since the confidentiality and integrity that cryptography guarantees. Homomorphic encryption (Gentry 2009) maintains consistency of computation over plaintext and ciphertext. By leveraging homomorphic encryption, computation can be carried out directly over ciphertexts without any decryption. That prevents any adversary from observing the corresponding plaintext during computations. Another substitutable cryptographic tool that provides similar features is secure multiparty computation (Yao 1986), which is interactive among multiple participants. By embedding a trapdoor into a ciphertext, multiple participants collaborate to resolve a specific function $f(x_1x_2x_3, \dots, x_n)$ without leaking x_i hold by participant P_i . Searchable encryp-

Network Privacy Surveillance and Privacy Protection, Fig. 2 Differential privacy interactive model

tion (Song et al. 2000) is proposed and applied to privacy protection while both searchability and confidentiality are vital in data management, such as encrypted database, private content-based image/information retrieval, etc. In keyword searchable encryption, a trapdoor for searching is embedded into ciphertext. Hence, a specific keyword can be matched by comparing trapdoor and ciphertext. In generally searchable encryption, novel encryption/index algorithms (order preserving encryption (Agrawal et al. 2004) and comparable encryption (Furukawa 2013), etc.) are introduced to construct secure index over massive data. Based on that index, a candidate set of searching result can be located, and further refined to derive an accurate result efficiently.

Privacy Quantification and Evaluation

Assuming that a trusted data curator holds a dataset D which about n individuals, and considering a non-interactive setting data publishing problem, the curator publishes a synthetic dataset aiming to protect individual privacy. From the perspective of information theory, differential privacy system can be seen as an information-theoretic channel which inputs original dataset D and outputs a synthetic dataset $\hat{D}$ (Alvim and Andrés 2011). We model original dataset as discrete random variable X and the receiving end observable outputs as discrete random variable Y . In this model we define privacy information source entropy $H(X)$ to

evaluate the uncertainty of original dataset. For the receiving an end observable outputs Y , we introduce the conditional entropy $H(X/Y)$ to evaluate remaining uncertainty after observed outputs Y , and quantitative leaking information in the information-theoretic channel as the mutual information $I(X; Y) = H(X) - H(X/Y)$ (Peng et al. 2016).

The Balance Between Privacy Protection and Usability

In practical applications, the privacy protection level of service data is inconsistent with its availability. For example, in dummy-based location privacy protection methods (Liu et al. 2017), with the increase of privacy protection level of the user location, which means the number of dummies is increasing, the time required for the service provider to check the database is improving constantly. In l -diversity data release privacy protection methods, with the increase of l , the fine-grained of released data is decreasing, thus reducing the data's availability (Cicek et al. 2014). Therefore, it is a hot topic in current research about how to trade off the privacy protection level of service data and its availability. Shown as follows, a game model between the data provider and the data user can be used to characterize this contradictory relationship.

Definition 2 (The game model between privacy protection level of service data and its availability). The game model between privacy protection

level of service data and its availability is a three-tuple $G = \{PAU\}$, where:

- $P = \{P_{Provider}, P_{User}\}$ is the set of rational participants. $P_{Provider}$ is the data provider, and P_{User} is the data user.
- $A = \{A_{Provider}, A_{User}\}$ is the set of rational participants' strategies. $A_{Provider} = a_{Provider}(\lambda)$ is the strategy set of the data provider in which $a_{Provider}(\lambda)$ represents the strategy chosen by the data provider $P_{Provider}$ based on his privacy protection requirements. $A_{User} = a_{User}(\lambda)$ is the data user's decision on whether to use the data sent by the data provider for statistical results.
- $U = \{u_{Provider}, u_{User}\}$ is the utilities set of rational participants. Based on the data provided by the data provider $P_{Provider}$, $u_{Provider} = Sec(\lambda) + QoS(\lambda)$ is the privacy protection and service quality enjoyed by him. And $u_{User} = u(\lambda)$ represents the data user's benefits, such as the privacy information inferred of the data provider $P_{Provider}$.

Key Applications

At present, the opening and sharing of data lead to a large number of privacy issues. Thus, some privacy-preserving applications works are required to solve them, such as anonymous processing, differential privacy processing, etc. In addition, to resolve the privacy disclosure issues in social networks, in some applications intelligent recommendations are included for privacy preference settings to their users. Last but not least, in many applications risk assessment of privacy leakage is also included before the users make decision on their on-line use.

Future Directions

In the future, with the development of artificial intelligence (AI), the traditional privacy preserving method may no longer be suitable for the application demands. To solve the problem of

the personal privacy can be sensed by machine learning technologies, and the methods based on generative adversarial networks will be the future directions of personal privacy preserving. The generative adversarial networks may be able to interfere machine learning models by adding a tiny and imperceptible perturbation to lead them misclassifying. Furthermore, to resist the risk of privacy leakage caused by AI technologies, some legislation and supervision cannot be avoided.

Network Selection in Heterogeneous Wireless Networks

Wei Song

University of New Brunswick, Fredericton, NB, Canada

Synonyms

Call assignment; Radio access selection

Definition

When the cellular networks are interconnected with the wireless local area networks (WLANs), there is a two-tier overlaying structure which offers both cellular access and WLAN access to a dual-mode mobile device within the WLAN-covered area. Ubiquitous coverage is provided by the cellular network (higher-tier), while WLANs (lower-tier) are deployed in disjoint hot-spot areas. Then, there comes the network selection problem of how to properly admit incoming traffic to the cell or WLAN. Specifically, a preferred target network, either a cellular cell or a WLAN, should be first selected based on various decision criteria by taking into account factors such as service type and network conditions of the two networks. A service request rejected by its first-choice network can just leave the system or further try to access the other network.

Historical Background

Nowadays, the wireless networks support heterogeneous wireless access technologies. The popular cellular networks and WLANs present perfectly complementary characteristics in terms of service capacity, mobility support, and quality-of-service (QoS) provisioning. On one hand, the fourth-generation (4G) cellular networks are spreading fast, providing ubiquitous wide-area coverage, QoS-guaranteed services, and

full-spectrum mobility support. On the other hand, IEEE 802.11-based WLANs are widely deployed in hotspot areas (e.g., offices, airports, and hotels), supporting high-rate and low-cost data services in the restricted small areas. The cellular/WLAN interworking offers an effective approach for sharing load and saving cost.

Many integration architectures have been proposed for cellular/WLAN interworking. According to the inter-dependence between the two networks, the integration architectures are classified into two categories, i.e., tight coupling and loose coupling. The interworking can be very tight with an integration at the radio access network (RAN) level or less tight with the integration in the cellular core network (CN). The interworking can also be loose with the two networks integrated beyond the core network and usually through an external Internet protocol (IP) network.

With tight coupling, the existing cellular infrastructure can be reused to a large extent, and it is possible to apply joint resource allocation to optimize overall system capacity. The main disadvantage of tight coupling is the high implementation complexity. An interworking unit equipped with a cellular-compatible interface is necessary to expose the WLAN to the cellular core or even the cellular RAN. On the other hand, the loose-coupling architecture can employ the pervasive IP technology to glue together the cellular network and WLANs. Although imposing minimal modification to the WLAN, loose coupling requires the cellular network to be augmented with extra functionalities such as Mobile IP. Nonetheless, loose coupling is relatively inefficient because of a long signaling path, redundant processing in the two networks, and a large number of network elements involved in management operations.

Foundations

With the cellular/WLAN interworking, many challenging research issues arise to take advantage of the complementary characteristics of the two different networks so as to enhance their strength and compensate for their limitation. The

key research problems include vertical handoff (i.e., the handoff between wireless networks of different access technologies), network selection, call admission control, and resource allocation. In fact, these research problems are closely related and need to be addressed jointly to achieve maximum interworking gain.

While the cellular network provides ubiquitous connectivity with wide-area coverage, WLANs are only deployed disjointly in hotspot areas. The cellular/WLAN interworking then results in an overlay structure, which offers both cellular access and WLAN access to dual-mode mobiles in the overlay area. First, when there is an incoming request, either an available cell or WLAN should be selected to accommodate the request. However, the selected network may accept or reject the call depending on its available resources and the admission control policy in place. For an unsuccessful initial assignment, the call can resort to the other network for access or just quit. In addition, existing calls in the integrated system can be dynamically migrated between the cellular part and the WLANs. For example, when sufficient resources are released from call completion or outgoing handoff, an existing call can be reallocated to a more desirable network according to current network conditions. The call reassignment is also referred to as take-back in some literature.

Together with the aforementioned network selection strategies, the admission control policies in the target networks need to be properly designed to limit the admissible traffic load and provide QoS assurance. It is vital to address network selection and admission control jointly in order to optimize the traffic placement and maximize the overall resource utilization. For example, as handoff dropping is more annoying than new call blocking, handoff calls should be prioritized over new calls in the admission control policy, e.g., by means of reserving guard channels, queueing handoff calls, and so on. Correspondingly, it is preferable to distinguish handoff calls from new calls in the network selection strategy as well. In addition, user location is another key factor for both network selection and admission control, since the accessible resources vary with locations.

Specifically, in order to efficiently utilize the integrated resources, the following unique characteristics of the integrated network should be considered in network selection and admission control.

- **Heterogeneous wireless access environment:** Aimed at different applications, the cellular networks differ from WLANs at the physical layer, medium access, and link control layers. For example, the cellular networks use allocation-based channel access such as code-division multiple access (CDMA) and orthogonal frequency-division multiple access (OFDMA). The centralized control and reservation-based resource allocation at base stations (BSs), together with proper admission control to limit the traffic load, enable fine QoS provisioning in cellular networks. In contrast, the channel access of most popular WLANs is contention-based random access, e.g., the mandatory distributed coordination function (DCF) of IEEE 802.11 WLAN. DCF adopts carrier sense multiple access with collision avoidance (CSMA/CA) and binary exponential backoff. The access point also needs to compete for access with other mobile devices and therefore behaves differently from the BS. Correspondingly, the service provisioning is in a best-effort manner without QoS assurance.
- **Hierarchical overlay network structure:** After four generations of evolution, the cellular networks have widely entrenched infrastructure, which provides almost ubiquitous connectivity and supports full-spectrum user mobility from fast highway vehicles to stationary users in an indoor environment. In contrast, WLANs are usually deployed disjointly in hotspot local areas, where the traffic intensity is typically much higher than surrounding areas. Thus, the cellular/WLAN interworking results in an overlay structure. Both cellular access and WLAN access are available to mobiles within WLAN-covered areas. The incoming traffic load should be properly shared between the overlay cell and WLAN for QoS enhancement, congestion relief, cost reduction, etc.

- **Multi-service traffic load:** Multi-service support has become an essential requirement for current wireless networks. Different services usually require different QoS deliveries. Real-time service such as voice and video are sensitive to delay, while the main concern for delay-tolerant data service is the throughput. Multiple services can take a good advantage of the complementary strength of the two networks. For example, benefiting from the centralized infrastructure, cellular networks can effectively serve real-time traffic with stringent QoS requirements. On the other hand, WLANs can be a good choice for elastic data service, which may experience traffic asymmetry at the uplink and downlink. The contention-based access of WLANs enables a virtually time division duplexing (TDD) mode to efficiently handle the load asymmetry and flexibly adapt to traffic elasticity. As seen, the service type is an important factor in network selection for cellular/WLAN interworking.
- **Location-dependent user mobility:** User mobility has been extensively studied for resource allocation in hierarchical cellular networks where microcells are overlaid with macrocells. However, many design principles are not applicable to cellular/WLAN interworking, although there exists a similar overlay structure. For WLANs deployed in indoor hotspots such as offices and hotels, the low user mobility within these areas results in a heavy-tailed residence time (Thajchayapong and Peha 2006). Consequently, a uniform mobility model becomes invalid for a large cell. As the user residence time in a cell or WLAN directly affects channel holding time, this new characteristic further complicates network selection.

Next, we introduce some representative approaches for network selection with cellular/WLAN interworking. These solutions often address network selection together with related issues such as vertical handoff, connection-level bandwidth allocation, call admission control, and load sharing.

Song et al. analyzed a simple and easy-to-implement network selection strategy, referred

to as WLAN-first scheme, where WLANs are always preferred by all services whenever the WLAN access is available, so as to take advantage of the low cost and large bandwidth of WLANs (Song et al. 2007b). An incoming service request rejected by a WLAN overflows to the cellular network to request admission if it is a new call, or remains in the cellular network if it is an ongoing call carried by the overlaying cell. Considering real-time voice service and interactive data service (such as Web browsing), this work derives the admission regions for the integrated network.

A service-differentiated network selection strategy is investigated in Song et al. (2005). Considering the distinct features of the cellular network and WLANs, it is essential to apply different network selection policies for delay-sensitive real-time traffic and delay-tolerant elastic data traffic. Due to the large cell size and ubiquitous coverage of the cellular network, it is preferable to first assign real-time voice calls to the cellular network. On the other hand, interactive data calls that accept elastic bandwidth can more efficiently utilize the large WLAN bandwidth. Hence, data service should attempt to access the WLAN first and only resort to the cellular network when the WLAN is congested.

To further reduce implementation complexity and enable flexible control, the service-differentiated principle in network selection can also be incorporated in a randomized selection policy. As proposed in Song et al. (2007a), an incoming voice (resp. data) call in the overlay area can select the covering cell or the WLAN according to a probability θ_v^c (resp. θ_d^c) and θ_v^w (resp. θ_d^w), respectively. Here, it is obvious that $\theta_v^c = 1 - \theta_v^w$ and $\theta_d^c = 1 - \theta_d^w$. The key problem is to determine these selection parameters according to traffic and mobility estimates. In addition, these parameters can be adapted to control the load sharing between the two networks. For example, θ_d^w can be increased appropriately if more data traffic needs to be offloaded to the WLANs.

In addition to the service type, many other factors can be considered in the network selection problem, e.g., user moving speed, chan-

nel condition, traffic load status, mobile device type, personal preference, etc. Correspondingly, different techniques can be applied to assimilate these factors and rank the candidate access options. The decision process in Bari and Leung (2007) uses noncompensatory and compensatory multiattribute decision-making (MADM) algorithms jointly on the network side to assist the mobile device to select the top candidate network. There are different MADM solutions such as multiplicative exponent weighting (Yoon and Hwang 1995), simple additive weighting (Zhang 2004), and the technique for order preference by similarity to ideal solution (TOPSIS) (Zhang 2004).

The network selection scheme in Song and Jamalipour (2005) is based on an integrated algorithm of analytic hierarchy process (AHP) and gray relational analysis (GRA). AHP quantitatively weights decision alternatives by hierarchical and pairwise comparison, while GRA ranks network alternatives efficiently through building a gray relationship with an ideal option.

Gelabert et al. studied radio access selection in heterogeneous multiaccess multiservice wireless networks (Gelabert et al. 2008). A 4D Markov chain is proposed accounting for two service types, generically voice and data, which are served over two access networks. The proposed analytical framework can be used to define a wide range of access selection policies taking into account several criteria such as service type, network conditions, and device type. Two service-based network selection schemes are compared with a load balancing scheme, a terminal-driven scheme, and a random policy. Especially, the service-based schemes indicate a tradeoff between the average data throughput per user and the total blocking probability.

In Si et al. (2010), application-layer multimedia QoS (e.g., video distortion) is considered as decision criteria for network selection, which is different from the focus of network-layer QoS, such as blocking probability, throughput, and resource utilization efficiency. The authors formulate the heterogeneous wireless networks as a restless bandit system, which has been widely

applied in operations research and stochastic control. With the restless bandit approach, the optimal network selection policy is derived in a fully distributed and scalable manner. Moreover, the application layer parameter, intra-refreshing rate, is adapted to further improve user experience with multimedia applications.

Game theory is another popular technique to investigate network selection with connection-level bandwidth allocation and admission control for heterogeneous wireless networks. Niyato and Hossain present a game-theoretic framework for a heterogeneous wireless access environment, in which a mobile user is able to connect to a WLAN, a wireless metropolitan area network (WMAN), and a cellular network simultaneously (Niyato and Hossain 2008). Two noncooperative games are formulated for the network-level bandwidth allocation to different service areas, and the connection-level admission control to arriving connections, respectively. Further, a bargaining game is formulated to obtain the capacity reservation thresholds so that vertical and horizontal handoff connections are prioritized over new connections.

In Yu and Krishnamurthy (2007), an optimal joint session admission control scheme is proposed for multimedia traffic in the cellular/WLAN integrated network. It is based on a semi-Markov decision process (SMDP) to maximize the overall network revenue with QoS constraints. Throughput and packet delay are considered as QoS constraints in the WLAN, while signal-to-interference (SIR) and SIR outage probability are considered for the CDMA based cellular network. An infinite horizon SMDP is formulated and solved by the linear-programming-based algorithms. The optimal joint admission control policy obtained thereby is found to be a randomized policy.

Key Applications

Network selection for heterogeneous wireless networks is fundamental in network resource allocation, QoS assurance, load sharing, vertical handoff management, and call admission control

so as to optimize multi-service provisioning and maximize overall resource utilization efficiency.

Network Slicing-Enabled Green C-RAN

Yi-Han Chiang and Yusheng Ji
Information Systems Architecture Science

[Green C-RAN with network slicing](#)

Definition

Network slicing is an emerging technology that allows mobile network operators (MNOs) to slice their physical networks into logical ones, thereby providing independent services to multiple mobile virtual network operators (MVNOs). With the incorporation of network slicing, physical network resources can be allocated in terms of network slices, each of which represents a virtualized and isolated network with reserved network resources.

Cloud radio access network (C-RAN) incorporates the concept of cloud computing into RANs, which generally consists of a baseband unit (BBU) pool and remote radio heads (RRHs). The BBU pool is located at a centralized site with abundant computing resources, while the RRHs are distributed antenna units that are deployed apart from the BBU pool. By pooling the BBUs of RRHs together, lower capital and operation expenditures (CapEx and OpEx) for MNOs can be envisaged.

Remote radio head (RRH) is a set of lightweight antenna units with its processing units partly or totally migrated to the BBU pool, but retaining its location at distant sites. RRHs are

connected to the BBU pool by delivering in-phase and quadrature (IQ) data through fronthaul (FH) links. Thanks to the resource pooling feature, the use of RRHs evolves as a cost-effective alternative (due to the simplified hardware architectures as compared to traditional macro base stations) and makes large-scale network deployments easier than before.

Historical Background

The emergence of mobile data tsunami as forecasted in Cisco (2019) has stimulated MNOs to search for next-generation wireless networks. To catch up with the explosive growth of mobile data traffic while keeping CapEx and OpEx at a minimum, network densification has been widely regarded as a promising solution in that it offers denser service coverage and higher capacity due to the massively deployed small cells, and benefits from lower transmit power consumption because of shortened last-mile distances. To manage such denser networks efficiently, MNOs are inspired to pay attention to C-RAN (I et al. 2014; Checko et al. 2015; Saxena et al. 2016; Alimi et al. 2018) in its benefits of better resource optimization and cost effectiveness.

In parallel with the standardization of 5G systems, network slicing (Zhou et al. 2016; Rost et al. 2017; Foukas et al. 2017; Zhang et al. 2017) has attracted growing research attention due to its flexibility and scalability to meet diverse requirements of future mobile networks. By means of network slicing, each physical network (owned by an MNO) can be dynamically sliced into several logical ones, thereby providing reserved network resources to individual MVNOs. In this way, a wide range of services (e.g., data, video and telephony) with distinct requirements (e.g., bandwidth, delay, reliability and privacy) from different MVNOs can be embedded in the same physical network.

In addition to boosting network capacity, plenty of existing works have been devoted to energy-saving issues (Arnold et al. 2010; Auer et al. 2011) in cellular systems, thereby saving CapEx and OpEx for MNOs. Thanks to the

centralized architecture, C-RAN can be smoothly integrated with network slicing while achieving network greenness. Since BBUs and RRHs will be initiated to serve user equipment (UE) for MVNOs, where BBUs and RRHs can incur power consumption in their computation and communication, respectively, they should be efficiently activated and utilized. One possibility for the energy conservation inspired by Wang et al. (2017), Aqeeli et al. (2018) and Yao and Ansari (2018) is that one BBU can serve a cluster of RRHs, and less active BBUs can lead to lower power consumption in the BBU pool. Another energy-saving opportunity from Ashraf et al. (2011), Holtkamp et al. (2014) and Chiang and Liao (2017) indicates that each RRH consumes power in its operation and radio transmission. As a consequence, the less the active RRHs, the lower the resulting power consumption. Altogether, how BBUs and RRHs can be activated and how BBU-RRH and RRH-UE mappings can be performed, while satisfying network capacity limits and user requirements, are decisive in green C-RAN with network slicing.

Foundations

A generic C-RAN architecture (as shown in Fig. 1) consists of a set $\mathcal{L}$ of BBUs (colocated in a BBU pool) and a set $\mathcal{M}$ of RRHs, where each RRH is connected to the BBU pool through a high-speed FH link, and the BBUs are controlled and managed by the MNO. On top of the C-RAN, there exists a set $\mathcal{V}$ of MVNOs, each of which has an independent set $\mathcal{N}_v$ of UE (each with a data rate requirement of R_n , $\forall n \in \mathcal{N}_v$) to serve. After receiving service requests from MVNOs, the MNO needs to serve the set $\mathcal{N} = \bigcup_{v \in \mathcal{V}} \mathcal{N}_v$ of UE.

In the BBU pool, an active BBU can be realized by initiating a virtual machine (VM), which can serve one or more UE. Clearly, the BBU-RRH mapping is either one-to-one or one-to-many. In addition, each BBU $l \in \mathcal{L}$ can only support up to $C_l^{\max}$ RRHs, due to its limited computing resources and FH capacities.

Each BBU/RRH can be activated or deactivated to reduce its operational power

consumption. Typically, such a deactivation can save energy effectively, since a non-zero energy dissipation can be attributed to operating in active mode. Therefore, operational power consumption can be lowered whenever a BBU/RRH can be deactivated.

Thanks to the centralized processing of C-RAN, multiple RRHs can cooperatively transmit to UE, thereby improving the received signal qualities. Suppose that universal frequency reuse is adopted by all RRHs to fully utilize the network spectrum of bandwidth B . Denote by SINR_n the received signal-to-interference-plus-

noise ratio (SINR) at each UE as

$$\text{SINR}_n = \frac{\sum_{m \in \mathcal{M}} p_{mn} H_{mn}}{I_n + N_0}, \quad \forall n \in \mathcal{N}, \quad (1)$$

where H_{mn} refers to the channel power gain from RRH m to UE n , N_0 is the noise spectral density at each UE, I_n aggregates the interfering powers experienced by UE n . In addition, $p_{mn} \leq P_m^{\text{tx}}$ is the transmit power allocated to UE n by RRH m , where P_m^{tx} is the RF output power of RRH m at its maximum load (namely RRH m 's transmit power budget).

Network Slicing-Enabled Green C-RAN, Fig. 1 An illustration of a network slicing-enabled C-RAN, where MVNO A requests for 2 BBUs and 3 RRHs, and MVNO B asks for 3 BBUs and 3 RRHs. After collecting

the demands from the MVNOs, the MNO simply activates 2 BBUs and 2 RRHs, in the way that network capacity limits and user requirements can all be met

The total power consumption is to aggregate the operational and transmit power consumption

of all BBUs and RRHs, which can be expressed as

$$\begin{aligned}
 p^{\text{tot}} &= \overbrace{\sum_{l \in \mathcal{L}} P_{R,m}^{\text{act}} y_m + \sum_{l \in \mathcal{L}} P_{R,m}^{\text{slp}} (1 - y_m) + \sum_{m \in \mathcal{M}} \sum_{n \in \mathcal{N}} \Delta_{R,m} p_{mn}}^{\text{RRH power consumption}} \\
 &+ \underbrace{\sum_{m \in \mathcal{M}} P_{B,l}^{\text{act}} z_l + \sum_{m \in \mathcal{M}} P_{B,l}^{\text{slp}} (1 - z_l) + \sum_{l \in \mathcal{L}} \sum_{m \in \mathcal{M}} \Delta_{B,l} q_{lm}}_{\text{BBU power consumption}},
 \end{aligned} \tag{2}$$

where $P_{R,m}^{\text{act}}$ and $P_{R,m}^{\text{slp}}$ are the power consumption of RRH m operating in active mode and sleep mode, respectively, and $P_{B,l}^{\text{act}}$ and $P_{B,l}^{\text{slp}}$ are those of BBUs. $\Delta_{R,m}$ and $\Delta_{B,l}$ represent the slopes of the load-dependent power consumption of RRH m and BBU l , respectively. The binary decision variables y_m and z_l indicate the activeness of RRH m and BBU l , p_{mn} is the transmit power of RRH m allocated for serving UE n , and q_{lm} indicates whether RRH m is associated with BBU l .

Mathematically, the problem of enabling network slicing to green C-RAN (NSGC) can be formulated as (for brevity, $\mathbf{p} = \{p_{mn}, \forall m, n\}$, $\mathbf{q} = \{q_{lm}, \forall l, m\}$, $\mathbf{y} = \{y_m, \forall m\}$ and $\mathbf{z} = \{z_l, \forall l\}$):

$$\begin{aligned}
 \min_{\mathbf{p}, \mathbf{q}, \mathbf{y}, \mathbf{z}} \quad & p^{\text{tot}}, \\
 \text{s.t.} \quad & \mathbf{C1: } B \log(1 + \text{SINR}_n) \geq R_n, \forall n \in \mathcal{N}, \\
 & \mathbf{C2: } \sum_{n \in \mathcal{N}} p_{mn} \leq P_m^{\text{tx}} y_m, \forall m \in \mathcal{M}, \\
 & \mathbf{C3: } \sum_{l \in \mathcal{L}} q_{lm} = y_m, \forall m \in \mathcal{M}, \\
 & \mathbf{C4: } \sum_{m \in \mathcal{M}} q_{lm} \leq C_l^{\text{max}} z_l, \forall l \in \mathcal{L}, \\
 & \mathbf{C5: } p_{mn} \geq 0, \forall m \in \mathcal{M}, n \in \mathcal{N}, \\
 & \mathbf{C6: } q_{lm}, y_m, z_l \in \{0, 1\}, \forall l \in \mathcal{L}, m \in \mathcal{M},
 \end{aligned}$$

where **C1** states that the achieved data rate should be high enough to meet each UE's data rate requirement, **C2** indicates that each RRH can allocate transmit powers to UE (up to its transmit power budget) only if it is operating in active mode, **C3** ensures that each active RRH is associated with exactly one BBU, **C4** presents that each active BBU can only accommodate a limited amount of RRHs, **C5** and **C6** refer to the decision variables of RRH-UE mapping, BBU-RRH mapping, the activeness of RRHs and BBUs, respectively.

In fact, finding an optimal solution to the NSGC problem is essentially NP-hard. Therefore, it is of more practical interests to look for an approximate solution with a polynomial-time complexity and a provably good performance guarantee.

Definition 1 Consider the NSGC problem as follows: does there exist a solution $(\mathbf{p}, \mathbf{q}, \mathbf{y}, \mathbf{z})$ such that the constraints **C1** to **C6** can all be satisfied, and the total power consumption p^{tot} is at most U ? The problem instance can be expressed as

$$\begin{aligned}
 & \text{NSGC}(\mathcal{L}, \mathcal{M}, \mathcal{N}, B, \{R_n\}, \{H_{mn}\}, \{C_l^{\text{max}}\}, \{P_m^{\text{tx}}\}, N_0, \\
 & U, \{\Delta_{R,m}\}, \{\Delta_{B,l}\}, \{P_{R,m}^{\text{act}}\}, \{P_{B,l}^{\text{act}}\}, \{P_{R,m}^{\text{slp}}\}, \{P_{B,l}^{\text{slp}}\}).
 \end{aligned}$$

Definition 2 (WEIGHTED SET COVER) Given a collection $\mathcal{C}$ of subsets of a finite set $\mathcal{S}$ with $\bigcup_{D \in \mathcal{C}} D = \mathcal{S}$ and a positive integer V . Does $\mathcal{C}$ contain a subcollection $\mathcal{C}' \subseteq \mathcal{C}$ with $\sum_{D \in \mathcal{C}'} W_D \leq V$, such that every element of $\mathcal{S}$ belongs to at least one member of $\mathcal{C}'$? The problem instance can be denoted by $\text{WSC}(\mathcal{S}, \mathcal{C}, V, \{W_D\})$.

Theorem 1 *The NSGC problem is NP-hard.*

Proof. Consider the restricted case of only one BBU, i.e., $\mathcal{L} = \{l^\circ\}$. Since the NSGC problem involves power allocation whereas the WSC problem does not have the analogous part, it is necessary make the data rate requirements low enough to ensure that **C1** can always be held for all UE. By carefully examining **C1**, it can be observed that the following fact holds: as $R_n \geq \bar{R}_n$, **C1** can be satisfied as long as each UE is served by an arbitrary one RRH with a uniform transmit power (i.e., $P_m^{\text{tx}}/|\mathcal{N}_{l^\circ}|$ for each $n \in \mathcal{N}_{l^\circ}$), where

$$\bar{R}_n = B \log \left[1 + \left(\frac{\sum_{l \in \mathcal{L}} |\mathcal{N}_{l^\circ}| (N_0 + \sum_{m \in \mathcal{M}} P_m^{\text{tx}} H_{mn})}{\min_{m \in \mathcal{M}} P_m^{\text{tx}} \cdot \sum_{m \in \mathcal{M}} H_{mn}} - 1 \right)^{-1} \right]. \quad (3)$$

Given with $R_n \geq \bar{R}_n$, it is apparent that the uniform transmit powers are always allocable.

The NP-hardness of the NSGC problem can then be proved by restriction. In particular, the NSGC problem can be restricted by allowing only instances with simply the active operational power consumption (by setting $\Delta_{R,m}, \Delta_{B,l}, P_{R,m}^{\text{slp}}$ and $P_{B,l}^{\text{slp}}$ to zeros) and binary channel states ($H_{mn} \in \{0, 1\}$). Other parameters can be chosen freely without affecting the following instance mapping. Now, consider an WSC problem instance of

$$\text{WSC}(\mathcal{S}, \mathcal{C}, V, \{W_D\}).$$

Then, the corresponding restricted NSGC problem instance can be obtained as

$$\text{NSGC} \left(\{l^\circ\}, \mathcal{C}, \mathcal{S}, 1, \{K_1, K_1, \dots\}, \{E_{Cs}\}, K_2, \{1, 1, \dots\}, |\mathcal{C}|, V, \{0, 0, \dots\}, \{0, 0, \dots\}, \{W_D\}, \{W_D\}, \{0, 0, \dots\}, \{0, 0, \dots\} \right).$$

where $K_1 = \log(|\mathcal{S}|/|\mathcal{S}|-1)$, $K_2 = |\mathcal{C}|$, $E_{Ds} = 1$ if $s \in D$ and 0 otherwise. Since the transformation between the restricted NSGC problem instance and the WSC problem instance can be run in polynomial time, the NP-hardness of the NSGC problem is thus proved. $\square$

Key Applications

Network slicing-enabled green C-RAN generally involves the dynamic operations of BBU/RRH activation, BBU-RRH and RRH-UE mappings, which can be adequately designed to support applications (e.g., enhanced mobile broadband

(eMBB), ultra-reliable low-latency communications (URLLC) and massive machine type communications (mMTC)) that require reserved network services, while heading towards network greenness.

[IP mobility management](#)

Definitions

Network-layer mobility management refers to the ability of a mobile node to maintain the IP address while it moves. In traditional IP net-

works, IP addresses are employed at the same time as host identifiers and locators. The former means that transport protocols in a TCP/IP stack operate based on a combination of IP addresses and ports as the identities for a communication between two processes. The latter means that IP addresses are also used as an aggregatable system of addresses that help to route packets toward their destination. The impact of mobility across different IP domains is observed in Fig. 1, where a mobile node has established a communication with an application server. Once the mobile node changes its IP address from MN IP1 to MN IP2, packets sent by the application server with destination IP address MN IP1 get lost in the network (i.e., IP address unreachable). In addition, the translation in the DNS system gets outdated due to the change of IP address of the mobile node; hence, if a communication is to be established from an external server to the mobile node, it will fail until the entry in the DNS system is updated.

A network-layer mobility management protocol intends to keep the same IP address of the mobile node even when the mobile node changes the point of attachment when moving among different IP networks. Therefore, the change of IP network becomes transparent to active applications and transport protocols running on top of IP.

Historical Background

A mobility management mechanism is in charge to handle two aspects: the location of the mobile device and the maintenance of the connections while the mobile user is in motion (Akyildiz et al. 1999). In general, when mobility support is provided with a mobility management protocol, the network is able to locate their mobile users, so that new connections directed to those users can be successfully established. Once a connection has been established, it should remain active while the user is moving to a new point of attachment, and the transition to the new service area should be as transparent to the user as possible.

Mobility management could be performed at different layers on the stack of communication protocols. For the specific case of network-layer

mobility management, it is related to protocols in charge to handle the IP assignment in order to provide IP address continuity when the node changes the point of attachment to the network.

As illustrated in Fig. 2, according to the domain of action, mobility management protocols provide global mobility when IP address continuity is enabled although the movement of the mobile node causes a change to the global, end-to-end routing of packets, including a change to the global IP address (Kempf 2007). Localized mobility management protocols provide IP address continuity under a single administrative domain (and typically, a single access network).

The first version of a network-layer mobility management protocol for IP networks was standardized at the IETF in the mid-1990s. The protocol, namely, IP Mobility Support – RFC 2002 (Perkins 2002) – was first standardized for IPv4 and later on for IPv6. Several extensions and variations in hierarchical networks, as well as updated versions, have been standardized ever since (cf. Key Proposals).

Key Proposals

In the most traditional form of classification, network-layer mobility management protocols have been categorized as host-based or network-based. The division refers to the entity responsible for detecting and managing mobility to maintain the IP address assignment. In the case of host-based mobility, it is the mobile node's responsibility, whereas in the case of network-based mobility, the network is in charge of detecting the node's movement and exchange all the signalling necessary to provide IP address continuity.

Host-Based Mobility Protocols

Among the category of host-based mobility protocols are the protocols Mobile IP and the Network Mobility (NEMO) Basic Support. Mobility support in IPv6 (MIPv6) was initially defined by the IETF in 2004, with an updated version being released in 2011 (Perkins et al.

Network-Layer Mobility Management, Fig. 1 Illustration of the effects of mobility in IP-based communications

Network-Layer Mobility Management, Fig. 2 Global and localized mobility management

2011). In general, MIPv6 enables the mobile node to keep using its home address (i.e., the IP address assigned in its home link), even when the node moves to a visited network. When the mobile node moves to a visited network, it configures an IP address, known as the care-of-address, through conventional IPv6 mechanisms such as stateless or stateful auto-configuration. This care-of-address allows the node to establish

communications at the new location, but it also serves for establishing an association, or “binding,” between the mobile node’s home address and the care-of-address. The binding is performed when the mobile node is away from the home network. At that point, the mobile node registers the newly acquired care-of-address with a router, known as the home agent, in its home network. Therefore, if a correspondent

node sends packets to the mobile node, they are first routed to the mobile node's home network, where the home agent encapsulates each packet with a new IP header and redirects them to the visited network (i.e., the extra header indicates the mobile node's care-of-address as the new destination). Then, the mobile node decapsulates and processes the original IP packets.

An optimized version to avoid the pass through the home agent has been also defined for MIPv6 (Arkko et al. 2007). If the correspondent node supports mobility, then the mobile node can inform about the new location directly to the correspondent node. As a result, packets coming from the correspondent node are routed directly to the visited network, with no need to be sent first to the home agent. This enhancement also requires a security procedure, called Return Routability, which permits the mobile node to prove that the claimed home address and care-of-address are indeed assigned to it, preventing in this way man-in-the-middle attacks.

In the case of NEMO Basic Support (Devarapalli et al. 2005), it is an extension to Mobile IP for the support of mobile networks instead of single hosts. Nodes in the mobile network are served by a mobile router, and they configure IP addresses from a mobile network prefix advertised by the mobile router. When the mobile router connects to an access router in a visited network, it acquires a care-of-address and establishes a tunnel with the home agent, similar to MIPv6. In this way, such tunnel is used for communications of the mobile network nodes with any correspondent node. Although the standard does not include an optimized version of NEMO BS, extensive research has been done to improve the performance of the protocol in terms of delay and throughput (Petander et al. 2006).

Network-Based Mobility Protocols

Proxy Mobile IPv6 (Gundavelli et al. 2008) is a network-based mobility management approach in which the network, on behalf of the mobile node, performs all the signalling required to provide IP mobility. An entity named the mobile access gateway detects new connections and exchanges proxy binding updates and proxy

binding acknowledgements (PBU/PBA) with a centralized entity known as the local mobility anchor (LMA). The LMA is a manager for network prefixes assigned to nodes inside the administrative domain. When a handover occurs, the new mobile access gateway notifies the new connection to the LMA (i.e., it sends a PBU). Then, the LMA identifies the MN and assigns the same network prefix to it (i.e., it replies with a PBA). In this way, every time the mobile node roams inside the PMIP domain, the node does not detect any changes at the network layer, and the mobility is transparent to upper layers in the stack of protocols.

Future Directions

A common characteristic of traditional IP mobility management protocols is the use of a centrally deployed mobility anchor in charge of managing traffic from millions of mobile nodes, which poses several problems since a small number of mobility anchors end up managing both mobility and reachability for mobile nodes. Since 2012, a new initiative at the IETF, namely, the Distributed Mobility Management – DMM – working group, proposes a distributed mobility management architecture and explores deployment practices of existing mobility protocols to satisfy distributed mobility management requirements (Liu et al. 2015). The working group considers solutions based on physical or virtualized networking functions and the possibility for a mobile node to select between the IP address in the visited network (i.e., care-of address) and the “permanent” IP address (i.e., home address) depending on the specific requirements of the application.

Neural communication; Neuronal signaling; Neuro-spike communication

Definitions

Neuronal communication or *neuro-spike communication* (NSC) is the method neurons use to transmit information, which is encoded into *spike* trains. This communication starts with propagation of spikes through *axon* of the input neuron until reaching the *axonal terminals* located at the end of the axon. This initiates the fusion of *vesicles*, i.e., packets of *neurotransmitters*, with cell membrane resulting in the release of neurotransmitters to the gap between input and output neurons, called *synapse*. After diffusing through the synapse, neurotransmitters bind to the respective receptors located on the surface of the postsynaptic neuron, which leads to opening of ionic channels and changing the postsynaptic membrane potential. If these changes are strong enough, the output neuron detects spike arrival, i.e., generates a spike.

Historical Background

Neuronal signaling, a natural phenomenon enabling communication at nanoscale, advocates the idea of nanoscale communication networks. Thus, it is a highly investigated intrabody nanonetwork to understand the communication paradigm underlying information transfer between nerve cells. In NSC, sensory or first-order neurons encode information from outside world into spike trains. This information is proposed to be either encoded in exact timing of the spike or in the spiking rate over a certain period of time, known as temporal and rate coding, respectively (Bear et al. 2007). These spikes are transmitted through neuronal network to reach higher brain regions for processing or memory storage. In the following, the physiology of NSC is briefly explained. Single-input single-output (SISO) NSC is comprised of three parts as shown in Fig. 1.

Axonal propagation Axon is the nerve fiber that conducts electrical impulses, known as action potentials or spikes, away from the cell

Neuronal Communication Channels, Fig. 1 Neural anatomy of communication among a pair of neurons (Ramezani and Akan 2018a)

body. Some axons are covered with fat layer called myelin, which works as an electrical insulation layer and results in faster conduction of spikes (Bear et al. 2007). Spikes were considered as all-or-none phenomenon for a long time; however, depending on the previously propagated spikes through the axon, spike shape can change during axonal transmission (Geiger and Jonas 2000; Feng et al. 2014; Ramezani and Akan 2017).

Synaptic transmission Information from one neuron to another neuron is transferred over a synapse. The synapses are of two types: (i) electrical synapses, called gap junctions, which are electrical links formed between two neurons, and (ii) chemical synapses, where information is transmitted through neurotransmitters, i.e., a type of chemical messengers, across synaptic cleft. However, the chemical synapses are the most common ones (Bear et al. 2007). Thus, most of the NSC studies are focused on chemical synapses, and the word synapse is usually used to refer to a chemical synapse in these studies. In presynaptic terminal, the neurotransmitters are stored in vesicles that are divided into three pools, i.e., reserve pool, recycling pool, and readily releasable pool (RRP), depending on their availability to be released in response to a

spike (Rizzoli and Betz 2005). It takes the longest to mobilize the vesicles in the reserve pool, while in RRP, vesicles are ready to be mobilized upon arrival of a spike.

Spikes are propagated through the axon until reaching the presynaptic terminal, where they lead to opening of voltage-gated calcium channels (VGCCs) allowing the influx of calcium ions. Increase in calcium concentration inside the cell initiates the fusion of vesicles from RRP with the cell membrane releasing neurotransmitters into the synapse. Different types of neurotransmitters are used for different functionalities of the brain such as glutamate, dopamine, and serotonin. These neurotransmitters diffuse through the synaptic cleft to reach the terminal of the receiving neuron, known as postsynaptic terminal (Bear et al. 2007).

Spike generation Released neurotransmitters bind to their respective receptors present on the postsynaptic terminal. This binding opens ionic channels that allow influx or efflux of ions resulting in the change of the postsynaptic membrane potential. This membrane potential change can either be excitatory, i.e., facilitating the output neuron to fire a spike, or inhibitory, i.e., inhibiting the neuron from firing a spike. Thus, these are termed as excitatory postsynaptic

potential (EPSP) and inhibitory postsynaptic potential (IPSP), respectively (Bear et al. 2007).

In real scenario, a postsynaptic neuron has multiple synapses, i.e., it receives input from multiple presynaptic neurons, where each input can produce EPSP or IPSP at their respective synapses. However, for spike generation, the membrane potentials are integrated at soma. If this accumulated change is larger than spike generation threshold, which depends on the previous stimulations the neuron has received (Kobayashi et al. 2009), the postsynaptic neuron generates a spike.

ICT Methods for Neuro-Spike Communication (NSC)

Engineering-based studies of neuronal signaling, which are from ICT point of view, aim to characterize different biological events involved in this communication to evaluate the communication theoretical performance of the brain and provide nanoscale communication paradigms (Balevi and Akan 2013; Malak and Akan 2013; Veletić et al. 2016a). In Manwani and Koch (2001), detection and estimation paradigms are used to calculate information transfer rate of a SISO NSC. In Balevi and Akan (2013), the performance of NSC is evaluated by deriving the probability of error detection in the output neuron. The rate region of synaptic communication is derived in Malak and Akan (2013) by investigating the multiple access to the output neuron. The same approach is used in Ramezani et al. (2017) to find the rate region of SISO NSC with multiple synaptic terminals between input and output neurons. An upper bound is derived for the capacity of SISO synaptic communication in Veletić et al. (2016b). The impact of spike generation on the performance of multiple-input single-output (MISO) NSC is investigated in Ramezani et al. (2018b). Recent studies have focused on the randomness in different processes involved in the NSC. The SISO NSC channel is studied in Maham (2015) under axonal noise. Moreover, the effects of variations in spike shape on the efficiency of synaptic communication are studied in Ramezani and

Akan (2018a) by modeling the gating of VGCCs and its impact on the release of neurotransmitters. Furthermore, the changes in the vesicle release probability with time due to unavailability of vesicles for release are considered in Ramezani and Akan (2018b) and Ramezani et al. (2018a) to find the capacity of vesicle release and synaptic communication, respectively. Results depicted that ignoring the variation in vesicle release probability leads to overestimation of the capacity of the NSC. Despite the recent efforts toward having a more accurate NSC model, the theoretical models still fail to comprehensively capture aspects of the neuron dynamics and their impact on the performance of this communication channel. Some of these aspects are (i) possible alterations in spike shape in healthy and disease-affected neurons, (ii) changes in synaptic strengths due to both short- and long-term plasticities, and (iii) variations in the spike generation threshold. In addition, experimental studies are needed to validate the accuracy of these theoretical models. In the remainder of this section, a modeling approach is explained for the NSC in which different sources of randomness are taken into account. In addition, the open challenges of this modeling approach are highlighted.

By discretizing time into windows of equal duration, i.e., Δt_s , where Δt_s is the duration of a spike (Ramezani and Akan 2018b), the block diagram of the SISO NSC is derived as shown in Fig. 2.

Input signal The input signal, i.e., S_n , indicated spike generation by input neuron in n th time slot, which is governed by Poisson process (Manwani and Koch 2001). Thus, the probability of having one spike at input is derived as $P\{S_n = 1\} = 1 - \exp(-\lambda \Delta t_s)$, where λ is the rate of the Poisson process.

Axonal propagation As a result of random opening of ionic channels, erroneous spikes might be added to the input spike train during axonal transmission (Maham 2015). Moreover, failures can happen during axonal propagation due to different diseases. Thus, in Fig. 2, P_a and P_b are used for the probability of erroneous

Neuronal Communication Channels, Fig. 2 Block diagram of NSC channel

spike generation and failure in spike propagation, respectively. Note that in this model, the spike is considered to be all or none, i.e., its shape does not change. However, variations in the spike shape during axonal transmission are recorded with the use of direct recording from axons (Jensen and Durand 2009; Sasaki 2013; Feng et al. 2014), which consequently affect the performance of NSC (Ramezani and Akan 2018a). Hence, further experimental studies are required to comprehensively distinguish source of the spike shape changes and their impact on the vesicle release process.

Vesicle release process Different models exist in the literature for vesicle release process including deterministic (Veletić et al. 2016a) and stochastic models, where the vesicle release process is modeled by a binary Z channel (Manwani and Koch 2001; Matveev and Wang 2000). Deterministic models fail to capture the trial-to-trial variability in the vesicle release process. In the stochastic models, the release probability is either considered to be fixed (Manwani and Koch 2001) or changing with time (Matveev and Wang 2000). The latter one is more accurate as vesicle release probability depends on the availability of vesicles for release, which changes with time. Utilizing the release model given in Matveev and Wang (2000), it is shown in Ramezani and Akan (2018b) that the probability of having N vesicles for release at the beginning of a time step can be derived based on a finite-state Markov chain by considering a pool-based vesicle release model. Then, the vesicle release probabilities P_e and ϵ can be derived according to the pool-based release model and the derived Markov chain.

Diffusion process Diffusion of neurotransmitters through the synapse follows Brownian motion. This is used in Khan et al. (2017) to derive the expected value of neurotransmitters concentration in the cleft t seconds after release by considering the synaptic geometries and neurotransmitter reuptake. Further studies are required to evaluate whether the randomness in diffusion process must be included in NSC model.

Neurotransmitter receptor binding If a neurotransmitter reaches to the vicinity of a post-synaptic receptor, it can bind to it with some probability, which depends on type of the receptor. As shown in Ramezani et al. (2018a), the probability of binding can be derived by utilizing the kinetic model of neurotransmitter receptor binding and the concentration of neurotransmitters near receptors.

Spike generation A simple spike generation model is derived by comparing the postsynaptic membrane potential with a constant threshold (Ramezani et al. 2018b). Accurate models must encompass the variations in the spiking threshold by time, for instance, by utilizing a multi-timescale adaptive threshold (Kobayashi et al. 2009).

Key Applications

The study of neural signaling from communication theoretical perspective will pave the way for development of bio-inspired nanonetworks for various applications requiring biocompatible net-

work paradigm as well as developing ICT-based treatment and diagnosis techniques for neurodegenerative diseases.

Nanoscale Transceivers and Artificial Synapses

ICT analysis of NSC can be exploited to implement artificial devices providing two-way communication in nanoscale. This enables the development of bio-inspired nanonetworks for various applications from biomedical to industrial and environmental fields (Akyildiz et al. 2008). Moreover, it can enable the technologies required for the realization of Internet of Bio-Nano Things (IoBNT) (Akyildiz et al. 2015). This gives rise to vast applications in healthcare including remote monitoring of patient's vital signs through the Internet, administering periodic dosage of drugs in patients, and repairing communication failure between vital organs and cells within the body.

Another application of these devices is communicating with neurons as artificial synapses, i.e., stimulating a neuron and detecting neural signals. For this purpose, there are three main methods to interact with neurons: electrical, chemical, and optical methods. First, the patch clamp method has been introduced by Sakmann and Neher (1984) to study electrophysiological activities in electrically excitable cells such as neurons and cardiomyocytes. Since then, the patch clamp method is the gold standard in electrophysiology. Inspired by this technique, high-density microelectrode arrays have been introduced to stimulate/detect neuro-spikes from lower number of neurons, e.g., biocompatible and transparent graphene electrodes are utilized for neural signaling in Kuzum et al. (2014). Electrical signaling can achieve high resolution with high number of electrodes; however, continuous electrical stimulation may cause stress in the target cell.

The second method is chemical stimulation in the form of neurotransmitters, which mimics the natural way of communication in chemical synapses. Thus, chemical stimulation does not create cell stress as in the electrical stimulation, but the interference is a significant chal-

lenge due to the diffusion of neurotransmitters to neurons that are not targeted. A hybrid device based on PEDOT:PSS electrodes, which is capable of chemical stimulation and electrical detection, is proposed for lowering the neural activity to control epileptiform activity by Jonsson et al. (2016). Chemical stimulation can be also exploited for neural stimulation by using excitatory neurotransmitters. Furthermore, optogenetics is a popular method for stimulating neurons. Engineered photoactive neurons are stimulated via specific wavelengths to create excitatory or inhibitory effects (Wirdatmadja et al. 2017). Optical stimulation provides accurate stimulation of target neuron with less noise, but requires biological modification of the neuron. At the end, these techniques have some advantages/disadvantages, and the current trend is to combine different techniques to exploit the advantages, e.g., a device having six electrodes, one optical waveguide, and two microfluidic channels was proposed by Park et al. (2017).

In addition to the interfacing with neurons, synaptic plasticity, i.e., the change in synaptic communication over time, can be artificially implemented by novel memory devices, i.e., memristive devices whose resistance depends on the previous currents (Alibart et al. 2013). Thus, memristive devices can mimic a synapse to realize long-term potentiation and depression of synapses. Memristive devices together with artificial synapses also pave the way for bio-inspired neuromorphic computation devices.

Diagnosis and Treatment of Neuronal Dysfunction

Most of the neurodegenerative diseases are the result of either abnormal interaction or loss of communication between neurons. For instance, in Alzheimer's disease, the capacity of brain to store and retrieve memories is degraded due to the loss of communication between neurons, i.e., due to loss of synapses (Sheng et al. 2012). Destruction of myelin sheath over axon results in multiple sclerosis, which reduces the information transfer rate through the affected network (Steinman 1996). Parkinson's disease is caused by falling dopamine levels in the brain, which

controls the vesicle release in neurons, which are responsible for information transfer between neurons (Harnois and Di Paolo 1990). Amyotrophic lateral sclerosis (ALS) causes death of motor neurons disconnecting the brain from the peripheral nervous nanonetwork. This is analogous to communication link failure in a network affecting the control of a brain on essential muscle activities (Leigh and Ray-Chaudhuri 1994). Another type of communication failure may occur due to spinal cord injury. Thus, unveiling the ICT-based characteristics of the disease-affected and healthy neuronal networks may enable the neurologists to diagnose diseases by detecting fundamental differences between the two networks.

Traditional treatments for neurodegenerative diseases and spinal cord injuries include medicine and rehabilitation techniques. The ICT-based understanding of nervous nanonetworks may also enable the development of new treatment techniques such as building artificial neural implants to cure communication failure in the nervous system. Advancements in this direction have been published in Capogrosso et al. (2016), where researchers have achieved leg movement in a paralyzed nonhuman primate by using implants in the motor cortex and spinal cord that communicate through wireless channel, bypassing the lesion in spinal cord. Neural interfacing also enables artificial retinas to restore loss of vision, artificial cochlea to restore loss of hearing, and artificial nose to restore loss of smell by converting sensory data to electrical signal that can be received by target neurons (Dobelle 2000; Eddington et al. 1978).

Conclusions and Future Research Challenges

In this article, an overview of neural signaling is provided from an ICT perspective including its various applications such as artificial synapses to interact with the nervous system in order to develop a bio-inspired nanoscale communication paradigm and ICT-inspired diagnosis and treatment methods for neuronal dysfunctions.

There are several open research challenges to be tackled for the ICT-based analysis of neural signaling and possible applications of these techniques. As molecular communication and nanonetworks being an emerging research field, there exist numerous theoretical studies on ICT-based investigation of neural signaling based on physiological data. Theoretical models often fail to capture the action potential shape variation, spike-timing-dependent plasticity, and synaptic long-/short-term plasticity. For this reason, the development of realistic neural signaling model supported by experiments stands as an important open research problem.

Artificial synapses also include many open research issues and implementation problems. The first issue is reaching the ultimate neural interfacing resolution, i.e., one-to-one pairing between electrodes and neurons. There exist some methods to interface with single neuron, but these methods have scalability problems, and many applications require interfacing with 100s or 1000s of neurons with the same device with low interference and noise. As these artificial devices need to operate inside living entities, i.e., body and brain of human/animal, biocompatibility of the devices is another significant problem. To this end, modern neural interfaces utilize novel biocompatible materials, e.g., PEDOT:PSS (Jonsson et al. 2016) and graphene (Kuzum et al. 2014). The lifetime of the devices is critical as well. There are two important factors that limit the lifetime of such devices. First, the device may lose its sensing/stimulating properties due to slowly dissolving properties of materials that are used. In addition, battery-powered devices offer limited lifetime that is prone to random depletions, and changing the batteries of invasive artificial synapses is often impossible. Thus, artificial synapses are required to have energy-harvesting techniques to empower its operations. For this purpose, wireless powered optogenetic devices with RF energy-harvesting capabilities are proposed by Wirdatmadja et al. (2017). Novel energy-harvesting techniques, e.g., energy harvesting from molecules, are required for continuous operation of artificial in-body devices.

Definition

Mirai, which means “the future” in Japanese, is a self-propagating malware that infects vulnerable networked IoT devices so as to turn them into part of a botnet that can be leveraged to perform large-scale distributed denial-of-service (DDoS) attacks.

Historical Background

The Mirai botnet was first discovered in August 2016 (Mal [2016](#)). It has been used in massive DDoS attacks, including an attack on KrebsOnSecurity in September 2016 which exceeded 600 Gbps (Krebs [2016](#)), an attack on OVH in September 2016 which exceeded 1 Tbps (Klaba [2016](#)), and an attack on Dyn in October 2016 (Hilton [2016](#)) resulting in the cripple of some well-known websites such as GitHub, Twitter, Reddit, Netflix, Airbnb, and many others (Williams [2016](#)). At its peak, Mirai infected 600k vulnerable IoT devices (Antonakakis et al. [2017](#)), whose IP addresses were spotted in 164 countries (Herzberg et al. [2016](#)). Since the source code for

Mirai was published on hackforums.net (Annasenpai 2016), the techniques can be digged deeply and may be adapted in other malware projects. The original creators of Mirai (i.e., Paras Jha, Josiah White, and Dalton Norman) has pleaded guilty in December 2017 (Department of Justice 2017) and sentenced to probation in September 2018 (Department of Justice 2018).

Foundations

Overview

In this chapter, we first present our analysis of the released source code of the Mirai malware for its architecture, scanning, and prorogation strategy (Antonakakis et al. 2017; Kambourakis et al. 2017; Ling et al. 2018). We then discuss why Mirai did not get attention in its prorogation phase until it deployed the DDoS attack. Finally, we present a new variant of Mirai that can improve the propagation speed. The goal of the study is to understand the impact of Mirai as both a worm and botnet.

Mirai Botnet

The Mirai botnet comprises four components as shown in Fig. 1: bots, a C&C (command and control) server, a scanListen server, and loader servers. The bots are a group of hijacked IoT devices via the Mirai malware. Starting with a scanning procedure on the port of the telnet service, the bots continue to perform a password dictionary attack using the username/password list already hardcoded in the Mirai malware. In this way, some vulnerable IoT devices are infected. The C&C server monitors the status of the botnet and controls the bots by obeying the commands from a botmaster, e.g., sending attack commands. On receiving the attack commands, the bots deploy various attacks such as distributed deny-of-service (DDoS) attacks. The scanListen server receives information of those newly discovered vulnerable IoT devices and relays it to the loader server. The loader server logs into a vulnerable device and infects it by executing the Mirai malware carried by the loader server. The IoT devices can be classified into three types:

(1) IoT devices that close the telnet service port, i.e., 23/2323 port. They are not accessible to the bots since the TCP connections are cut off permanently; (2) IoT devices that open the telnet service port but their username/password is absent in the username/password list of Mirai. The bots can perform the brute force attack against them but can never successfully compromise them; (3) IoT devices that open the telnet service port and their username/password is available in the list of Mirai. These devices can be compromised. Figure 1 illustrates the propagation procedure of Mirai. The step-by-step process is explained as follows.

- **Step 1 – Bots scanning IoT devices:** The propagation starts with a single IP, which is treated as a bot to ensure its consistency. The bot scans and detects vulnerable IoT devices over the Internet. The bot selectively probes the 23/2323 port of public IP addresses through TCP SYN scans. Note that some IP addresses are whitelisted by Mirai, including those of the US Postal Service, the Department of Defense, the Internet Assigned Numbers Authority (IANA), and IP ranges belonging to Hewlett-Packard and General Electric. Once a TCP SYN/ACK packet is acquired from an IoT device, a TCP connection is to be established between the bot and the IP address of the device. In order to log into the telnet server, the bot randomly selects a pair of usernames/password from its dictionary and tries it out to check whether the login is successful. By default, the dictionary has altogether 62 pairs of usernames/password. However, the password cracking trials are no more than ten times for a target.
- **Step 2 – Bots reporting information to scanListen server:** After a bot compromises a vulnerable IoT device, it reports the information of the device to the scanListen server, including the IP address, the port, and the username/password of the target. The domain name and port of scanListen server are also hardcoded into the malware.

New Variants of Mirai and Analysis, Fig. 1

Propagation process of Mirai

- **Step 3 – scanListen server relaying information to loader server:** The scanListen server receives the information of a compromised IoT device from the bot and then forwards it to the loader server.
- **Step 4 – Loader server installing Mirai:** The loader server first builds a TCP connection with the compromised device and then logs onto the device with the cracked username/password. After its login, the loader server starts detecting file transmission tools like *wget* or *ftp* on the target system. If a transmission tool is available, the Mirai malware is directly downloaded from the loader server and executed. Otherwise, the loader server connects to the telnet port of the target, reads a tiny binary file whose function is similar to that of *wget*, and writes *echo* into the target device. The hex characters from the binary file constitute the string for *echo*. Then the output stream of *echo* is redirected into a file and saved at the target device. Therefore, the binary file is transmitted from the loader server to the target. By executing the file, the Mirai malware can be downloaded from the loader server. Once the Mirai is executed, it shuts down Telnet, SSH, and HTTP server on the compromised device to avoid the login of other malwares or administrators. Mirai also

binds to port 48101 for the assurance that only one instance of the malwares is running on this device.

- **Step 5 – Bot registering with C&C server:** Once the Mirai malware is installed and executed on a vulnerable device, the device builds a TCP connection, registers with the C&C server, and gets involved in the Mirai botnet. The domain name and port of the C&C server are hardcoded into the malware. Then the bot performs Step 1.
- **Step 6 – Botmaster commanding bots to conduct attacks:** A botmaster can command the bots to perform attacks by sending instructions via the C&C server. The Mirai malware can be activated to launch various attacks like UDP DoS attack, TCP DoS attack, HTTP attack, and GREP attack.
- **Step 7 – Botnet attacking a target:** Once the C&C server receives the attacking instructions from the botmaster, it conveys the commands to the bots. Finally, the bots perform attacks against a target.

Scanning Strategy

The scanning algorithm of the released source code of the Mirai is worth studying since it is the key to its propagation speed. Therefore, we thoroughly analyze the Mirai scanning

Algorithm 1: Mirai Scanning Algorithm

Require: (a) μ - the number of SYN probes sent by Mirai each time, (b) m - the size of a table, (c) <i>table</i> - TCP connection table, (d) <i>table[i]</i> - store the <i>i</i>th TCP socket in <i>table</i>, (e) <i>table[i].state</i> - TCP connection state of the <i>i</i>th entry of <i>table</i>, e.g., connecting or connected. Ensure: Discover the vulnerable devices <pre> 1: while TRUE do 2: if time interval since last SYN probe $\geq 1s$ then 3: Send μ probes using a raw socket 4: end if 5: while TRUE do 6: Read SYN+ACKs packets from the raw socket 7: if error no data for reading no entries in table then 8: break 9: else if the <i>i</i>th entry of <i>table</i> is empty then 10: Build a connection, table[i].state = connecting 11: end if 12: end while 13: for $i = 1 : m$ do 14: if the connection in table[i] times out then 15: if table[i].state == connected then 16: re-connect(try times < 10), otherwise free table[i] 17: else if table[i].state == connecting then 18: free table[i] 19: end if 20: else if table[i].state == connecting then 21: Set the table[i] in write file descriptor set (wr fdset) 22: else if table[i].state == connected then </pre>	<pre> 23: Set the table[i] in read file descriptor set (rd fdset) 24: end if 25: end for 26: Select the write and read file descriptors 27: for $i = 1 : m$ do 28: if table[i] in wr fdset then 29: if connection error for table[i] then 30: free table[i] 31: else if connection success for table[i] then 32: table[i].state = connected 33: end if 34: end if 35: if table[i] in rd fdset then 36: while TRUE do 37: if connection error for table[i] then 38: re-connect(try times < 10), otherwise free table[i] 39: break 40: else if no data for reading then 41: break 42: else if data for the last command then 43: if login success then 44: report to scanListen server 45: else if login fail then 46: re-connect(try times < 10), otherwise free table[i] 47: end if 48: else 49: send one command 50: end if 51: end while 52: end if 53: end for 54: end while </pre>
---	---

algorithm in Algorithm 1. It is discovered that Mirai malware uses a uniform scanning strategy. Specifically, Mirai randomly scans public IP addresses and then randomly selects a pair of usernames/password from a hardcoded list for the dictionary attack. The TCP SYN scanning technique is employed to probe the 23/2323 port of a device for the purpose of determining whether the port is open. As can be seen from the Mirai source code, 160 IP addresses are randomly selected as target for the bot to scan. The bot sends TCP SYN packets to those IP addresses by using a raw socket. Then the raw socket is checked so as to obtain SYN+ACK packets.

As long as the bot receives a SYN+ACK packet, it establishes a TCP connection with the IP address in the non-blocking mode and records the connection in a table. After checking the raw socket and recording the connections, the bot checks the status of all TCP connections in the table. If a TCP connection fails to be built within 5 s, the bot will give up the connection request.

Conversely, if the TCP connection to the telnet port of an IP is established successfully, the bot will select a pair of usernames/password at random from the hardcoded list. Meanwhile, according to the feedback from the target device, the login can be verified as either a success

or a failure. If the bot receives no response from the device in 30 s, the login is deemed as a failure, and another trial goes on. The bot cuts off the unsuccessful connection and builds a new TCP connection to guess a random username/password again. However, such trials are only limited to ten times for Mirai to crack the username/password of a target IP.

Why Mirai Did Not Get Attention During Propagation

Since Mirai propagation did not cause the large-scale network congestion in the Internet in contrast to the propagation of Code Red worm (Zou et al. 2002), Mirai did not get attention during the propagation. To shed light on this phenomenon, we perform extensive simulations of Mirai propagation and analyze the time of TCP connection setup between a bot and a telnet port opened device to reflect the network state.

We simulate the original Mirai propagation using NS3. Recall that we divide the IP address space into three categories. We use empirical data to set the number of the devices in each category. Mirai grows to a peak of 600,000 infections at the end of November 2016 (Antonakakis et al. 2017), and the total number of IP addresses is 3,417,112,576 besides the IP addressed in the Mirai whitelists. Therefore, the proportion of vulnerable IoT devices is 0.0176%. Additionally, according to the results shown in ZoomEye (Zoo 2017), 11.1% online hosts open the telnet ports. To simplify the calculation, we round the proportions of the devices with open telnet ports and vulnerable telnet services to the nearest integer. Thus, in our simulation, we assume 10% of IoT devices in the IP space open the telnet port and 1% of the devices with the telnet service are vulnerable. Assume that the total number of devices in our simulated network is 65536. By using Monte Carlo method, we select 6325 devices that open telnet port, and 64 devices can be compromised by Mirai malware. Due to the limitation of computing power of IoT devices, the empirical results from Figure 6 in Antonakakis et al. (2017) show that the scanning bandwidth of 80% bots is smaller than 2000 Bps. Since the size of a TCP SYN scanning packet is 74 bytes, most bots can only probe around 30 IP addresses

to scan their telnet ports in each round, rather than 160 IP addresses used in the Mirai source code. Thus, we change the scanning rate to 30 in our simulation. Figure 2 illustrates the network topology used in the simulation experiment. We use the NS3 global routing by building a global routing database for the topology using a Dijkstra Shortest Path First (SPF) algorithm, and we set the throughput of devices and routers as 1000 Mbps. The TCP connection setup time between a bot and a telnet port opened device is used to determine if the network is congested. Figure 3 illustrates that the Mirai does not cause network congestion by using empirical parameters in the simulation. Therefore, we can infer that the infected devices cannot generate a large amount of propagation traffic due to the limited computing power of vulnerable IoT devices.

Besides the limitation of IoT device computing power, another reason why Mirai does not cause network congestion is that the proportions of devices with open telnet port and vulnerable telnet service, respectively, are small. We assume the bot can probe 160 IP addresses in each round as the source code set and set two proportions in Table 1. The NS3 simulation results in Fig. 3 show that until we set 40% of IoT devices in the IP space with open telnet port and 50% of the devices with telnet service that are vulnerable, the time of TCP connection setup becomes longer. At that point, the Mirai propagation has caused network congestion. Therefore, Mirai cannot cause network congestion by scanning and infecting a small number of devices with open telnet port and vulnerable telnet service.

According to the real-world observation (Antonakakis et al. 2017), the proportion of devices with open telnet port and vulnerable telnet service are much lower than the 40% and 50%, respectively, and the limitation of IoT devices computing power cannot probe 160 IP addresses every round either. Therefore, Mirai did not cause network congestion and get attention during the propagation.

New Mirai Variants

We design new scanning strategies in order to boost the propagation. In contrast to the malware

such as the Code Red worm (Zou et al. 2002) that exploits software vulnerabilities, the Mirai malware not only scan the devices to discover

the open telnet port but also crack the username/password using a hardcoded dictionary so as to successfully infect IoT devices. Therefore, the propagation speed of Mirai is much slower than that of the Code Red worm.

New Variants of Mirai and Analysis, Table 1 The proportions of devices with open telnet port and vulnerable telnet service

10%	50%
20%	50%
40%	50%

New Variants of Mirai and Analysis, Fig. 4 The Mirai propagation speed using different cracking strategies

New Variants of Mirai and Analysis, Fig. 5 The Mirai propagation speed using different password cracking times

tries at most 10 times on a target, we can derive $q = [1 - (61/62)^{10}]$. Our variant of Mirai does not try the same password/username pair more than once. If the bot tries at most ten times on a target as the original Mirai, q can be improved to $q = 10/62$. The simulation result in Fig. 4 shows that non-repeat username/password pair try strategy can improve the Mirai propagation speed.

The value of q varies as the username/password cracking times change. Based on the analysis of the original Mirai scanning strategy, we carry out Mirai propagation simulations on a scale of username/password cracking times. The cracking times are set at 5, 15, 20, 25, and 30, respectively. The simulation results are displayed in Fig. 5. It is observed that with the number of attempts increased (i.e., q increases), the rise of the propagation speed ensues. Another observation is that as the number of attempts increases, the gain (acceleration) of the propagation speed falls. Thus we can devise a new variant of Mirai by keeping the username/password cracking times at 20 so as to fasten the Mirai propagation speed.

Future Directions

In this chapter, we study Mirai and propose new Mirai variants. We carefully introduce the propagation process of Mirai. Extensive NS3 simulations suggest that if the number of vulnerable devices is small, infected devices would not cause network congestion. This is why Mirai did not get attention during its propagation. To understand the potential impact of future Mirai attacks, we study new scanning strategies of Mirai that may adopt a non-repeating username/password cracking strategy and raise the number of cracking attempts so as to significantly boost the propagation speed. Our work in this chapter raises the alarm again for the IoT device manufacturers to better secure their products.

Definition

Non-Orthogonal multiple access (NOMA) is a multiple access method proposed by NTT DoCoMo for the next-generation (5G) mobile network. NOMA is a type of non-orthogonal multiplexing where users are multiplexed in the power domain, which is not sufficiently utilized by previous wireless mobile systems. Specifically, signals from different users are superposed at the transmitter side and separated at receiver by using successive interference cancellation (SIC). Note that in some articles, “NOMA” is used as a general name for any scheme that multiplexes users in a non-orthogonal manner, instead of the specific scheme described above. In such articles NOMA proposed by NTT DoCoMo normally is renamed as power domain NOMA (PD-NOMA).

Historical Background

Multiple access (MA) scheme has been regarded as a key technology to distinguish each generation of wireless communication systems in the past decades. In the existing wireless systems,

orthogonal multiple access (OMA) has been widely used from first-generation (1G) mobile communication system to 4G. Well-known frequency division multiple access (FDMA) for 1G, time division multiple access (TDMA) for 2G, code division multiple access (CDMA) for 3G, and orthogonal frequency division multiple access (OFDMA) for 4G are all primarily OMA schemes. In these OMA schemes, users are multiplexed orthogonally in either the frequency, time, or code domain so that mixed signal can be separated at receiver with low complexity.

While OMA can effectively minimize inter-user interference with a relatively low implementation complexity, its spectral efficiency needs to be further improved in order to meet the requirements in next-generation (5G) wireless mobile network such as supporting ultrahigh data throughput, massive connectivity, low latency, etc. To accommodate such demands, NTT DoCoMo proposed a downlink NOMA scheme (Higuchi and Kishiyama 2012; Saito et al. 2013; Benjebbour et al. 2015) where multiple users are multiplexed in the power domain at transmitter side and demultiplexed at receiver side by using SIC (Mazen et al. 2003).

The standardization of NOMA starts from being proposed to 3GPP LTE Release 13 (3GPP 2014). Then a study item (SI) under the name of “multiuser superposition transmission (MUST),” which is a downlink version of NOMA, is approved (3GPP 2015a). More details on MUST can be found in 3GPP (2015b). Though initially proposed as a downlink scheme, existing works show that NOMA can also be applied in uplink (Zhang et al. 2017; Takeda and Higuchi 2011), and the standardization of uplink NOMA is currently under evaluation (3GPP 2016).

Foundations

Figure 1 illustrates the downlink NOMA with a simple one base station (BS) and two user equipments (UEs) case. The transmission bandwidth allocated to two UEs is assumed to be 1 Hz. In NOMA, signals for two UEs are superposed by using Superposition Coding (SC) (Cover 1971)

Non-orthogonal Multiple Access, Fig. 1 Simple comparison between basic downlink NOMA and OMA (OFDMA)

at transmitter side. Denoting the signal for UE- i , $i \in \{1, 2\}$, as x_i where $\mathbb{E}[|x_i|^2] = 1$, the coded signal at transmitter is

$$x = \sqrt{P_1}x_1 + \sqrt{P_2}x_2.$$

P_i is the transmit power allocated to UE- i , and the sum of P_i is restricted to P , i.e., $P_1 + P_2 = P$. In this example P_i is set as $P_1 = 0.2P$ and $P_2 = 0.8P$. Then the received signal at UE- i is

$$y_i = h_i x + w_i,$$

where w_i denotes that Gaussian noise including intercell interference and the power density of w_i is N_0 . h_i is the complex channel coefficient from BS to UE- i . In downlink NOMA, SIC is implemented at UEs, and the optimal decoding order is in the order of increasing channel gain normalized by noise and intercell interference, i.e., $\frac{|h_i|^2}{N_0}$ (Saito et al. 2013; Benjebbour et al. 2015).

In the two-UE case above, assuming $\frac{|h_1|^2}{N_0} > \frac{|h_2|^2}{N_0}$, UE-2 does not need to perform SIC since it

comes first in the decoding order. Therefore, UE-2 decodes its received signal x_2 directly treating x_1 as interference, and the throughput of UE-2 can be represented as

$$R_2 = \log_2 \left(1 + \frac{P_2|h_2|^2}{P_1|h_2|^2 + N_0} \right).$$

Different with UE-2, UE-1 first decodes x_2 to subtract its component from the received signal y_1 . The throughput at UE-1 decoding x_2 can be then represented as

$$R_{1 \rightarrow 2} = \log_2 \left(1 + \frac{P_2|h_1|^2}{P_1|h_1|^2 + N_0} \right).$$

As $\frac{|h_1|^2}{N_0} > \frac{|h_2|^2}{N_0}$, $R_{1 \rightarrow 2} > R_2$ is guaranteed which means x_2 can be completely decoded at UE-1 assuming SIC process at UE-1 is error-free. After subtracting x_2 from y_1 , the throughput of UE-1 decoding its own signal x_1 is

$$R_1 = \log_2 \left(1 + \frac{P_1|h_1|^2}{N_0} \right).$$

In comparison with NOMA, the throughput of each UE in OMA (OFDMA) systems shown in Fig. 1 can be derived as

$$R_1^o = \frac{1}{2} \log_2 \left(1 + \frac{P|h_1|^2}{N_0} \right),$$

$$R_2^o = \frac{1}{2} \log_2 \left(1 + \frac{P|h_2|^2}{N_0} \right),$$

assuming the bandwidth and the transmit power are allocated to each UE equally. When $\frac{|h_1|^2}{N_0} = 20$ dB and $\frac{P|h_2|^2}{N_0} = 0$ dB, (Saito et al. 2013) numerically compared throughput of each UE between NOMA and OMA and demonstrated that the corresponding gains of NOMA from OMA are 32% and 48% for UE-1 and UE-2, respectively. Besides the numerical example shown here, the performance gain of NOMA is also theoretically analyzed in Ding et al. (2014).

The gain of NOMA comes from the multiplexing gain which is translated from the channel gain difference between two UEs through using SC at transmitter side and SIC at receiver side. Although in NOMA the transmit power allocated to a single UE can be lower than that in OMA, i.e., the transmit power of UE-1 is $0.2P$ and $0.5P$ for NOMA and OMA, respectively, both UEs can benefit from being scheduled more bandwidth. While NOMA relies on advanced receiver processing ability such as SIC, the expectation for evolution of processing ability of user devices is reasonable, generally following Moore's law. The merits of NOMA can be summarized as following (Dai 2015; NTT-DOCOMO 2014):

1. Improved spectral efficiency: As shown in the example above, NOMA can offer higher spectral efficiency for both UEs. This advantage of NOMA over OMA can also be explained from the perspective of information theory. As proofed in Tse and Viswanath (2005), NOMA with SC at transmitter side and SIC at receiver side can achieve the optimal capacity region of the downlink broadcast channel. However, OMA is not able to achieve so.
2. Massive connectivity: Different with OMA, the number of supported users in NOMA is

not strictly limited by the amount of available resources and their scheduling granularity. Therefore, NOMA can be used to address the challenges of massive connectivity.

3. Robust performance gain: NOMA transmitter does not rely much on instantaneous channel state information (CSI), which requires feedback signaling from UEs, to perform multiplexing. Therefore the robust performance gain can be expected irrespective UE mobility and signaling latency.

Key Applications

There have been many standardization activities on the implementation of NOMA in 5G wireless mobile networks. Particularly, in 3GPP (2015b) the performance of MUST, the downlink version of NOMA, is comprehensively studied, and the conclusions are drawn as:

- MUST can increase system capacity as well as improve user experience in certain scenarios.
- MUST is generally more beneficial when the network experiences higher traffic load.
- MUST is generally more beneficial in user-perceived throughput for wideband scheduling case, compared to subband scheduling case.
- MUST is generally more beneficial in user-perceived throughput for cell-edge UEs, compared to other UEs.
- MUST-far UEs can be legacy UEs when QPSK is applied to MUST-far UEs or the most two significant bits in the modulation symbol are assigned to far UE.

Based on the advantages of MUST listed above, the implementation of MUST in some scenarios of 5G networks can be envisaged such as machine-to-machine (M2M) communications, ultradense networks (UDN), and mMTC (Recommendation ITU-R M.2083: IMT Vision 2015; Ding et al. 2017) where massive connections and the IoT functionality of 5G are required.

Definitions

Non-orthogonal multiple access (NOMA) refers to multiple access schemes that can enable two or more users to be served by the same base station in a single orthogonal resource block (e.g., time slot, subcarrier, spreading code) simultaneously.

Background

Due to the rapidly increasing traffic demand and the scarcity of the radio spectrum, multiple access is necessary for cellular systems to serve a large number of users. Each generation of wireless cellular systems is characterized by a specific multiple access scheme. In particular, frequency division multiple access (FDMA), time division multiple access (TDMA), code division multiple access (CDMA), and orthogonal frequency division multiple access (OFDMA) are utilized in the first-generation (1G), the second-generation (2G), the third-generation (3G), and the fourth-generation (4G) systems, respectively. As FDMA, TDMA, and OFDMA are orthogonal multiple access (OMA) schemes, each orthogonal resource block in the frequency and time domains can only be used to serve a single user, which is not spectrally efficient. On the other hand, CDMA requires that the chip rate has to be much higher than the supported data rate, which is very difficult to be implemented when the supported data rate is as high as 10 Gbps. These multiple access schemes are not able to support the typical use cases of the fifth-generation (5G) systems, which have very diverse quality of service (QoS) requirements, e.g., extremely high data rates, massive connection density, and ultralow latency.

As a promising multiple access technique to meet the QoS requirements of 5G systems, non-orthogonal multiple access (NOMA) has recently received considerable attention (Saito et al. 2013; Ding et al. 2014; Wong et al. 2017). The key idea of NOMA is to allow two or more users to be served in one orthogonal resource block simultaneously so as to enhance the spectral efficiency. Different variants of NOMA schemes have been proposed, including power-domain NOMA (Saito et al. 2013), sparse code multiple access (SCMA) (Nikopour and Baligh 2013), pattern division multiple access (PDMA), and low density spreading (LDS). Power domain NOMA is a single-carrier NOMA scheme, where the NOMA users' signals are transmitted in the same subcarrier. On the other hand, SCMA, PDMA, and LDS are multi-carrier NOMA

schemes, where each NOMA user's signal is spread over multiple subcarriers. Due to its simplicity and efficiency, power-domain NOMA is discussed in the rest of this entry.

Power-Domain NOMA

With power-domain NOMA, multiple users can be served simultaneously by a single base station using the same frequency channel and spreading code by allocating different transmit powers to the users. Power-domain NOMA can be applied in both downlink and uplink transmissions. Consider the two-user downlink NOMA scheme as an example, as shown in Fig. 1. The base station superimposes the signals intended for two users. The user experiencing a worse channel condition (e.g., U_1) is allocated a higher transmit power than the user experiencing a better channel condition (e.g., U_2). The user allocated a higher transmit power (e.g., U_1) decodes its own signal directly by treating the signal intended for the other user (e.g., U_2) as co-channel interference. On the other hand, the user allocated a lower transmit power (e.g., U_2) decodes its own signal after performing successive interference cancellation (SIC) to remove the other user's signal.

By accommodating two or more users in one orthogonal resource block, NOMA has the potential to significantly enhance the spectral efficiency, which can be utilized to achieve high system throughput (Zhou and Wong 2017), to support massive connectivity (Mostafa et al. 2017), and to reduce the medium access delay (Liang et al. 2017). Compared to OMA, NOMA can achieve a balance between system throughput and user fairness. Due to these advantages, NOMA, termed as multiuser superposition transmission (MUST), has been specified in the 3rd Generation Partnership Project (3GPP) Long-Term Evolution Advanced (LTE-A) standard (3GPP 2016). In addition, NOMA, termed as layered division multiplexing (LDM), has also been included in the digital TV standard (ATSC 3.0) (Zhang et al. 2016).

Transmit power allocation among the paired NOMA users plays an important role in determin-

Non-orthogonal Multiple Access (NOMA),

Fig. 1 Downlink power-domain NOMA transmission

ing the performance of power-domain NOMA. The outage probability and the sum rate of power-domain NOMA under the fixed and cognitive radio based transmit power allocation schemes were studied in Ding et al. (2016). An optimal transmit power allocation scheme was proposed in Choi (2016) to maximize the sum rate of the paired NOMA users when either the instantaneous or statistical channel state information (CSI) is available at the base station. On the other hand, user pairing is another aspect that is critical to the performance of NOMA. It has been demonstrated in Ding et al. (2016) that the performance gain of NOMA over OMA is greater when the users with more diverse channel conditions are paired. Based on the level of CSI (e.g., instantaneous channel gain, user's distance) available at the base station, different user pairing strategies can be utilized.

Cooperative NOMA and mmWave-NOMA

Due to its compatibility, NOMA can be combined with many communication technologies, including cooperative communication, millimeter-wave (mmWave), multiple-input multiple-output (MIMO), and visible light communication (VLC), to further enhance the network performance. For simplicity of explanation, two-user power-domain NOMA scheme is considered here. For two-user NOMA, the user located closer to the base station is

referred to as the near user, and the other user is referred to as the far user. Both cooperative NOMA and mmWave-NOMA schemes are briefly discussed as follows.

1. **Cooperative NOMA:** Based on the principle of NOMA, the far user shares the radio channel and the transmit power with the near user. Compared to OMA, the achievable performance of the far user is degraded. As the near user has to decode the signal intended for the far user before decoding its own signal, the near user can act as a relay and help forward the signal to the far user, which can effectively enhance the reception reliability of the far user.

By exploiting this feature, a cooperative NOMA scheme was proposed in Ding et al. (2015). The cooperative NOMA transmission can be divided into two phases. In the first phase, the base station broadcasts the superimposed mixture of the signals. In the second phase, the near user acts as a half-duplex relay and forwards the signal intended for the far user. After receiving the signal, the far user can decode its own signal by utilizing different combining techniques (e.g., selection combining, maximum ratio combining). The half-duplex cooperative NOMA scheme requires an additional time slot for relay transmission. To address this issue, a dynamic decode-and-forward (DDF)-based cooperative NOMA scheme was proposed in Zhou et al. (2017), which allows a half-duplex relay to provide a cooperative diversity gain without

the need of additional time slots. In particular, the near user decodes the superimposed signals based on partial reception, where the reception duration depends on the instantaneous channel gain. As soon as both signals are successfully received, the near user switches to the transmit mode and forwards the signal to the far user until the end of the time slot. As a result, both the superpositioned transmission and the cooperative diversity gain can be achieved in one time slot.

2. **mmWave-NOMA:** Due to the large amount of spectrum resources available in mmWave frequency bands, mmWave communication is a key enabling technology for the 5G systems. It is suitable for small-cell communications with coverage area of 200 m. Different from sub-6 GHz frequencies, mmWave frequencies (i.e., 30–300 GHz) suffer from higher path loss and penetration loss. Due to a smaller wavelength, multiple antennas can be deployed at the base station to achieve directional beamforming and exploit the array gain to ensure sufficient received signal power. The coexistence of mmWave and NOMA techniques for the 5G systems has recently been studied (Ding et al. 2017a,b).

Due to the directivity of mmWave transmission, the base station has to align its beam with the paired NOMA users' channels for the best system performance, which would introduce non-negligible pilot overhead. In order to reduce the protocol overhead required for channel estimation, the authors in Ding et al. (2017b) proposed an mmWave-NOMA scheme with random beamforming. Specifically, the base station equipped with multiple antennas forms transmit beams based on a random angle. Tools from stochastic geometry are utilized to analyze the outage probability and sum rate. By taking into account the hardware constraint that a practical circuit can support a limited number of phase shifts, the authors in Ding et al. (2017a) proposed a finite resolution analog beamforming scheme in massive MIMO and mmWave networks. Although the transmit beams are not perfectly aligned with the users' channels, mmWave-

NOMA can still achieve higher sum rates of the paired NOMA users than mmWave-OMA.

Conclusions

NOMA is a key enabling technique for 5G systems, and it can be combined with many communication techniques (e.g., massive MIMO, cooperative communication, mmWave) to achieve high system throughput, massive connectivity, and low latency. This entry reviewed the development, the basic concept, and the applications of NOMA. The examples of cooperative NOMA and mmWave-NOMA demonstrated the performance gain of NOMA over OMA.

University of Technology, Beijing, China

Synonyms

[Vehicular network data offloading](#)

Definitions

A new architecture is introduced to efficiently utilize the potential resource from connected vehicles and to mitigate the congestion problem in other data networks. Delay-tolerable data traffic is offloaded from the data networks to the connected vehicle networks without extra infrastructure/hardware deployment. An optimal distributed data hopping mechanism is also introduced to enable delay-tolerable data routing over connected vehicle networks. The next-hop decision optimization problem is formulated as a partially observable Markov decision process (POMDP). Simulation results are also presented to demonstrate the performance improvement of the proposed scheme.

Historical Background

Boosted by the rapid growth of data-generating devices, such as various types of sensors, smartphones, tablets, video game consoles, surveillance cameras, augmented reality devices, and wearable electronics, among others, the exponential increase in the volume of data has imposed significant pressure on the current communication networks (Szymanski 2013). Congestions at backhaul, backbone, and access networks could cause serious degradation in performances including data rate, packet loss rate, and delay, especially for the services with strict quality-of-service (QoS) and/or quality-of-

experience (QoE) requirements (Habachi et al. 2013).

As resources become the key constraint in communication networks, recent efforts on improving the QoS/QoE are made in two directions: utilizing more resources and utilizing resources more efficiently (Zhang et al. 2014a). Infrastructure deployment provides extra bandwidth, processing, and storage resources for the networks, while millimeter wave and terahertz communication technologies are exploiting new available spectrum resource. Besides, promising technologies, such as small cell, cognitive radio, massive multiple-input multiple-output (MIMO), and network function virtualization (NFV), contribute significantly to improving the resource utilization efficiency. Nevertheless, higher service quality is achieved at the increased costs on capital expenditures (CAPEX) and operating expenses (OPEX), due to the deployment and maintenance of extra infrastructure or hardware introduced by the above technologies.

However, a large portion of data traffic does not require high QoS, and thus extra costs on QoS improvement for such traffic could be a waste (Koo et al. 2007). For example, in content delivery networks (CDNs), delay of hours is acceptable when the popular contents are pushed to the servers at the edge of the network. In big data industries, high delay would not seriously affect the performance of some data backup services. Another scenario is the personal data that is delivered from one local data center to another as the data owner travels from one location to another to minimize the data obtaining delay. This personal data delivery could possibly tolerate high delay as well. Note that such delay-tolerable traffic also has the delay constraints or lifetime. The only difference is that its tolerable delay is much higher than delay-sensitive traffic. Aiming at satisfying various QoS requirements of different types of services while minimizing the costs, priority-based schemes have been widely studied to deliver delay-sensitive traffic with higher priority and treat delay-tolerable traffic as best-effort services (Zhang et al. 2014b). Unfortunately, since the total amount of com-

munication resources is limited and the traffic load becomes heavy, delay-tolerable traffic may have very little delivery chance, and thus the probability of successful delivery within its delay constraints could be low.

On the other hand, with the rapid development of technologies on connected vehicles and vehicular networks, millions of roadside units (RSUs) and vehicles equipped with communication, computing, storage, and positioning devices will be connected to form a worldwide network (Uhlemann 2015). Vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications, enabled by IEEE 802.11p and dedicated short-range communication (DSRC) technologies, allow road safety, driver assistance, and infotainment data transmission with up to 27 Mbps data rate (Kenney 2011). Furthermore, vehicular delay-tolerant networks (DTNs) have been widely studied recently, considering the vehicle networks that may lack continuous network connectivity due to the highly dynamic topology. With the embedded storage and communication capabilities of the vehicles and RSUs, data can be delivered in a “store-carry-forward” manner, taking advantage of the mobility of the vehicles (Isento et al. 2013). An in-depth analysis of the different proposals for vehicular DTNs is studied, and the DTN proposals are classified according to the type of knowledge needed to route messages in Tornell et al. (2015). However, current research on vehicular DTNs ignores the interaction with other existing data networks and focuses on delivering the data generated from (such as road safety and driver assistance data) or required by (such as traffic condition and infotainment data) the vehicular networks themselves, of which the data traffic is light, and thus the vehicle network resource utilization efficiency is low.

Connected Vehicle Network for Delay-Tolerable Data Delivery

To efficiently utilize the potential resource from connected vehicles and to mitigate the congestion problem in data networks, a new architecture is

**Offloading
Delay-Tolerable Data
Traffic to Connected
Vehicle Networks, Fig. 1**

An example of the
proposed architecture

proposed, in which delay-tolerable data traffic is offloaded from the data networks to the connected vehicle networks without extra infrastructure/hardware deployment. Delay-tolerable data is optimally scheduled to deliver over data networks and/or connected vehicle networks, according to the delay constraints.

The architecture proposed in this chapter is presented in Fig. 1. Connected vehicles and RSUs with embedded computing, storage, and positioning devices cooperate with each other and form a connected vehicle network. IEEE 802.11p- and DSRC-based technologies are adopted for wireless communications among the vehicles and RSUs. In this network, road safety, driver assistance, and other vehicle-related information are transmitted with higher priority, while spare network resources are utilized to deliver delay-tolerable data. Besides, vehicles and RSUs are also connected to the Internet via

other data networks, including cellular, WiFi, asymmetric digital subscriber line (ADSL), and fiber-to-the-home (FTTH) networks, among others. Data networks usually have better QoS performance with higher costs, compared to the hop-by-hop communications in the connected vehicle network.

With this architecture, a delay-tolerable file, no matter it is from/to the connected vehicle network or not, is segmented into equal-size data blocks and delivered over the connected vehicle network and/or other data networks, depending on the network condition and the delay constraints of the data blocks. In other words, the connected vehicle network and other data networks cooperate to schedule the data block delivery, in such a manner that delay-sensitive data traffic is delivered roughly over data networks, and connected vehicle networks are utilized mainly for delay-tolerable data blocks.

In the connected vehicle network, each vehicle or RSU has the information on its location and moving direction and keeps the direct connection with its neighbors within its one-hop communication range. A delay-tolerable data block is delivered toward its destination in a hop-by-hop and distributed manner. At the beginning of each time slot, the current storage of the data block, which denotes the device that has the data block in its storage, makes the offloading and/or hopping decision on which network should be utilized to deliver the data block, whether to keep the data block in the current storage or not and, if not, which neighbor it should be transmitted to. The decisions are made according to the delay constraint, the location of the destination, and the moving information of the current storage and its neighbors. Then, the data block is kept in the current storage or transmitted to the next-hop device. If the deadline of a data block is close, data networks may be selected as the next hop to guarantee that the data block is delivered to its destination on time.

Problem Formulation

In this section, the next-hop device decision problem is formulated as a partially observable Markov decision process.

System State Space

Decisions are made according to the information on the current storage and the neighbors, as well as the distance and angle to the destination. Thus, we define the system state as a group of destination angle, the moving direction of the current storage, the moving indicator of the current storage, the distance to the destination $d(k)$, and the successful-transmission indicator of the neighbors. Here, the moving indicator of the current storage is set to 1 or 0, if the current storage is moving or not, respectively.

Actions and Policies

The action $a(k)$ of the current storage is the decision on the offloading and/or hopping. The current storage needs to decide whether the data block will be transmitted over the vehicle network or the data networks. If data networks are selected, the data block will be transmitted to the data network and then delivered to its destination in the next time slot. If not, the current storage makes the decision on whether to keep the data block in the current storage, and if not, which neighbor the data block should be transmitted to. Let $a(k = 1)$ denote that the data block is transmitted over data networks, $a(k) = 0$ denote that the data block is kept in the current storage, and $a(k) = \beta$ denote that the data block is transmitted to a neighbor with the moving direction β .

Observations and State Transitions

The successful-transmission indicator of the neighbors may not be fully observable at each time slot. Fortunately, it can be estimated according to the observations on the neighbors of the current storage. As the system state transits from $s(k)$ to $s(k + 1)$ under action $a(k)$, an observation $o(k)$ is generated with the conditional probability $\text{Prob.}(o(k)|s(k + 1), a(k))$. Under action $a(k)$, the system state $s(k)$ is a Markov process, with the one-step transition probability $\text{Prob.}(s(k + 1)|s(k), a(k))$, or $P_s^a(i, j)$ for short, where $\hat{s}_i$ and $\hat{s}_j$ are the realizations of $s(k)$, and $\hat{a}_i$ is the action taken at t_k .

Objective and Reward

Our objective is to minimize the costs and successfully deliver the data blocks to their destinations within the required time constraints. We use $R(k)$ to represent the immediate reward obtained in each time slot:

$$R(k) = \begin{cases} R_{\text{arrive}} - C_{\text{Veh}}, & \text{if } d(k) \neq 0, a(k) \neq 0, d(k + 1) = 0, \\ -C_{\text{Veh}}, & \text{if } d(k) \neq 0, a(k) \neq 0, d(k + 1) \neq 0, \\ R_{\text{arrive}} - C_{\text{DN}}(d(k)), & \text{if } d(k) \neq 0, a(k) = 0, \\ 0, & \text{otherwise,} \end{cases} \quad (1)$$

where R_{arrive} is the reward obtained by successfully delivering the data block to its destination, C_{veh} is the cost to use the connected vehicle network for delivering the data block in each time slot, and $C_{\text{DN}}(d(k))$ is the cost to use the data networks for delivering the data block to the destination. Note that $C_{\text{DN}}(d(k))$ depends on the distance $d(k)$ from its current location to its destination.

Then, the decision optimization problem can be represented as:

$$g^* = \operatorname{argmax}_{g \in \mathbf{G}} \sum_{k=1}^K \gamma^{K-k} R(k), \quad (2)$$

where γ is the discount factor, $0 < \gamma < 1$. Finite horizon is considered for the data block transmissions. Consequently, no reward can be obtained if a data block fails to arrive at the destination before t_K , i.e., $\sum_{k=1}^K \gamma^{K-k} R(k) \leq 0$ if $d(K) \neq 0$.

Solving the POMDP Problem

With the system state space $\mathbf{S}$, action space $\mathbf{A}$, observation space $\mathbf{O}$, transition probabilities P , and system reward R , a POMDP tuple $\langle \mathbf{S}, \mathbf{A}, \mathbf{O}, P, R \rangle$ is formed. Many existing algorithms, including low-complexity heuristic ones, have been proposed to solve it by value and policy iterations and belief state updating and successfully applied in various scenarios, such as robotic control, task assignment, and radio resource management, among others (Padmanabhan et al. 2015; Young et al. 2013; Krishnamurthy 2011; Zhao et al. 2007; Si et al. 2009). Due to the space limit, details of these algorithms are omitted in this chapter.

Data Hopping Process

With the multitasking capability of the storage devices and the media access control (MAC) protocols that enable multiple orthogonal channels for sending and receiving, it is straightforward to assume that a storage device is capable to send and receive data blocks simultaneously. At the beginning of each time slot, the current storage device updates its observation and calculates the

optimal decision $a^*(k)$ based on the observations. Based on $a^*(k)$, the data block is kept in the local storage or transmitted to the next-hop device.

Simulation Results and Analysis

In this section, simulation results are presented to demonstrate the significant performance improvement of the proposed scheme.

Simulation Scenario

In our simulations, we consider a $10,000 \times 10,000$ m area, where 20,000 vehicles move along the roads at the average velocity $v = 8.33$ m/s (30 km/h). The average distance between two adjacent intersections is 300 m. When a vehicle arrives at an intersection, it stops and waits with the probability $P_{\text{wait}} = 0.75$ and the maximum waiting time $T_{\text{wait}} = 120$ s. We assume that the delivery delay requirement of the delay-tolerable data blocks is 18,000 s (5 h) and the data block size $B = 480$ Mbits = 60 MBytes. DSRC technology is adopted to enable wireless communications between connected vehicles and/or RSUs, of which the communication range $L_{\text{range}} = 200$ m and the achievable data rate $H = 16$ Mbps. Besides, we adopt $\tau = 120$ s as the time slot length, $R_{\text{arrive}} = 500$ as the successful delivery reward, $C_{\text{veh}} = 1$ as the cost to use the connected vehicle network in each time slot, and $C_{\text{DN}}(d(k)) = 100d(k)$ as the cost to use the data network to deliver the delay-tolerable data block.

The performance of our proposed optimal scheme is compared with three other schemes, including “data network only” (only data network is utilized to deliver the data), “connected vehicle network only” (only connected vehicle network is utilized, with optimal data block scheduling), and “random walk” (only connected vehicle network is utilized, with random data block scheduling).

System Reward Comparison

In Figs. 2, 3, and 4, we compare the performance of system reward, which is defined by Eq. (1). With different time slot length from 0.5 to 4 min, Fig. 2 demonstrates that the proposed scheme

Offloading Delay-Tolerable Data Traffic to Connected Vehicle Networks, Fig. 2 System reward comparison with different time slot length τ

Offloading Delay-Tolerable Data Traffic to Connected Vehicle Networks, Fig. 3 System reward comparison with different data block delay requirement

provides the highest reward compared to the other three schemes. If only the connected vehicle network is used to deliver the delay-tolerable traffic,

the system reward is lower due to that some data blocks may not arrive at the destination storage within the required time limit and then R_{arrive} is

Offloading Delay-Tolerable Data Traffic to Connected Vehicle Networks, Fig. 4 System reward comparison with different vehicle density w_{veh}

not obtained. The reward of the “data network only” scheme does not change with the different values of time slot length. Data networks always guarantee the short delay of the data blocks, and the costs depend only on the distance from the source to the destination storage. The reward from the “random walk” scheme is the lowest, because a large number of data blocks are not delivered to the destination storage by the time limit. The reward of the proposed scheme and “data network only” grows first but decreases when the time slot length is greater than 2.5 min, indicating that there exists an optimal time slot length to maximize the reward.

The system reward performance is shown in Fig. 3. Obviously, our proposed scheme achieves the highest system reward, and the reward of our scheme and “connected vehicle network only” schemes grows with longer acceptable delay of the data blocks, due to which more data blocks can arrive at the destination within the delay constraint. However, the “random walk” scheme fails to obtain higher reward, because longer delay constraint only leads to more hops before dropping a data block and higher cost as a result.

We can draw the similar conclusion from Fig. 4 that the proposed scheme significantly improves the system reward performance compared to all other three schemes. In this figure, the average vehicle density w_{veh} that ranges from 10 to 50 per km is obtained by $L_{\text{road}}/N_{\text{veh}}$, where L_{road} is a constant and N_{veh} varies.

Key Applications

Offloading delay-tolerable data traffic to connected vehicle networks is one of the key technologies in heterogeneous networks of Internet and vehicular networks. It efficiently utilizes the potential resource from connected vehicles and mitigates the congestion problem in data networks without extra infrastructure/hardware deployment.

Definition

An oligopoly refers to a market in which only a few (typically two to four) companies compete with each other to offer a resource or service to users. Such market structures typically arise in industries that are difficult for companies to enter, e.g., due to government regulations or the need for significant initial investment. In wireless networks, oligopolies can be found in markets for wireless connectivity, i.e., selling users access to wireless networks. In the cellular connectivity market, for instance, cellular providers generally need government spectrum licenses to operate, and significant investment is needed to build out a cellular network. Since spectrum is limited and rarely auctioned off, new providers may

find it hard to obtain spectrum access and break into the market. In the USA today, this market is dominated by Verizon, AT&T, Sprint, and T-Mobile.

Historical Background

Wireless service providers have sold their users access to cellular data since the 1990s, when second-generation (2G) wireless networks first became available. In the mid-2000s, wireless speeds increased with the release of first 3G and then 4G networks. At the same time, users' demand for wireless data began to increase exponentially, fueled by the release of the iPhone in 2007 and the growing popularity of smartphones. This popularity in turn drove cellular providers to further upgrade their networks, with LTE introduced around 2010 in North America, Europe, and Asia. These complementary trends have contributed to large growth in the number of subscribers as well as the volume of wireless data used by existing subscribers. Yet in the midst of this growth, cellular providers in the USA and other countries attempted to dampen competition by requiring users to purchase 2-year contracts and "locked" phones that would only function on a single provider's network. In doing so, they created effective "parallel monopolies," with few users switching between providers (Joe-Wong et al. 2015). Since 2016, however, cellular providers in the USA have begun to offer unlocked phones to users, allowing them to more freely switch between providers and opening the market to more oligopolistic competition.

As demand for wireless data grew, the limit on publicly available spectrum for cellular connectivity created congestion on cellular networks, fueling an opportunity for new types of business models. Many providers showed significant interest in pricing mechanisms to incentivize changes in user demand patterns, for instance, offering users discounts at uncongested times in order to incentivize them to shift their usage from congested to uncongested times (Sen et al. 2015). Cellular providers also began to

explore offloading data usage to other types of wireless networks. WiFi, for instance, is now a near-ubiquitous presence in urban environments. Much work has been devoted to the idea of using WiFi offloading as a solution to cellular network congestion, with some studies showing that such offloading has significant potential to alleviate congestion (Lee et al. 2013). Indeed, wireless networks encompass much more than cellular networks; they include not only WiFi technology but also femtocells, Bluetooth, etc. Such technologies have become increasingly important for the Internet of things (IoT) as more devices gain wireless connectivity (Wang et al. 2017).

As some providers explored offloading and pricing solutions to growing network congestion, newer providers began to enter the market, promising users better service at lower prices. Virtual Internet service providers (ISPs), sometimes known as MVNOs (mobile virtual network operators), rent physical capacity from a single cellular provider and resell it to end users, often at a discount. In recent years, some virtual ISPs have begun combining resources on cellular networks managed by different ISPs to off-load data between them. Competition from these virtual ISPs promises to change the structure of the wireless data market.

Foundations

Traditional oligopoly models from economic theory serve as a useful starting point for investigating oligopoly pricing in wireless networks. However, wireless networks have unique characteristics that are generally not found in oligopolies. In particular, users on such networks experience externalities from other users, e.g., due to congestion. These negative externalities affect the nature of competition between wireless networks and may encourage users to utilize multiple networks in order to avoid congestion (Cheung and Huang 2015). Moreover, some users can subscribe to multiple wireless networks at once, e.g., cellular and WiFi networks. This effect is particularly

important when modeling offloading scenarios, in which competing wireless network providers may provide different services. For instance, WiFi often has higher throughput than LTE networks but generally has a smaller coverage area. In economic terms, these providers offer differentiated products.

Oligopoly models: Oligopoly pricing can often be modeled as the outcome of a game. The three most common models are called the Cournot, Bertrand, and Stackelberg models. The Cournot and Bertrand models assume that there are two existing providers offering a homogeneous product (i.e., users do not intrinsically prefer one provider over the other) and consider providers that, respectively, compete on the basis of product quantity and price. The Stackelberg model considers the behavior of an incumbent provider and a potential competitor that wishes to enter the market (Sen et al. 2013). In each model, the traditional analysis assumes that all providers attempt to maximize their individual profits. The analysis then focuses on finding the Nash equilibrium, a point at which no provider can increase its profit by changing its decisions.

The Cournot and Bertrand models are rarely used in a wireless context, as they do not capture the externality or coverage characteristics of wireless networks. Stackelberg models, however, can be used to model the entry of heterogeneous wireless technologies into the market, e.g., a provider introducing femtocells (Ren et al. 2013). In a Stackelberg model, an incumbent provider can decide which prices to charge for its services, knowing that another provider may later attempt to enter the market. This provider is called the leader of the game, since it moves first. The entrant provider can then respond to the leader; it is called the follower of the game. Since the leader can anticipate the follower's decision, it often has more market power. Stackelberg games are solved with *backward induction*, i.e., first solving for the follower's optimal actions or best response as a function of the leader's action and then solving for the leader's optimal action given the follower's best response.

Modeling product differentiation: Wireless networks can encompass many different technologies with different characteristics. Variants of a Hotelling location model are often used to capture this product differentiation. In such models, users are assumed to lie along a continuum between two providers; they experience a cost of choosing each provider that is proportional to their distance to the provider. In a wireless context, this continuum can model physical distances between a user and a base station or the cost of switching to another provider (e.g., the inconvenience of signing up for a new data plan). This virtual or physical distance between providers models users' intrinsic preferences for different providers. Users then decide to subscribe to a provider based on these intrinsic preferences, the quality of service and coverage offered, and the prices charged by each provider.

Key Applications

Wireless offloading models: Variants of the Hotelling model can be used to study the role of pricing in wireless offloading (Joe-Wong et al. 2015). In this case, users might choose between subscribing to a cellular network, a cellular network supplemented by WiFi hotspots, or no network at all. Users may be modeled as lying on a continuum between subscribing to a network or not subscribing; different users would then make different subscription choices. A key feature of such a network is that due to externalities (i.e., more users leading to more congestion), the number of users on the network influences users' satisfaction from using the network. Thus, users' decisions would be influenced by not only their location along the continuum and the prices charged but also by the number of other users subscribing to each provider. As a greater proportion of users subscribes to the cellular provider, for instance, congestion will increase, driving users to subscribe to the WiFi-supplemented network. One can then show that these dynamics

reach an equilibrium and that the prices offered can influence the equilibrium number of users on each network (Joe-Wong et al. 2015).

Stackelberg game models have also been used to analyze subscription decisions for heterogeneous wireless technologies (Duan et al. 2014). In such models, a cellular or WiFi provider might play the role of a leader, with users playing the role of followers and deciding whether to subscribe to the provider and how much data they will use. The provider can then decide which types of pricing to offer, given these user decisions. Variants of the model include having global and local WiFi providers negotiate with each other to provide a larger WiFi coverage area for users.

Other works in this space have shown significant economic benefits to offloading with a single cellular provider (Lee et al. 2014). Subscription models, however, capture only the months-long timescale of users' subscription decisions. Another aspect to oligopoly pricing in the context of heterogeneous networks is users' shorter-term decisions of when to use which type of network, given that they sometimes have access to WiFi hotspots. This switching may be complicated by the energy expenditures required to switch between networks, as well as different energy usage in cellular and WiFi networks (Yu et al. 2016). These decisions may also incorporate pricing considerations, e.g., if users have a monthly cap on their cellular data usage and must decide when to off-load data throughout the month so as not to exceed this cap (Im et al. 2016). Such models require going beyond traditional oligopoly pricing and may incorporate dynamic programming or other online optimization methods.

Virtual Internet service providers: Recent innovations in the wireless data market have led to the creation of virtual ISPs, which combine resources from multiple physical ISPs. Stackelberg models can be used to model the resulting economic interactions: the virtual ISP can act as a leader of the game, deciding how much to charge users and which providers to rent capacity from. Physical providers, knowing these

decisions, can then play the role of followers and decide whether to partner with the virtual ISP. Finally, users can follow these provider decisions when deciding whether to subscribe to the virtual ISP (Zheng et al. 2017a). Such models can also be generalized to include WiFi connectivity as one of the features of a virtual ISP data plan (Zheng et al. 2017b).

Future Directions

With the demise of fixed-term contracts and the rise of unlocked devices in the USA, we expect to see more oligopolistic wireless markets in the coming years. These measures are already fueling more competition between providers, with some even offering discounts for new users who defect from other providers. We may also soon see more providers offering data plans that combine the physical resources of multiple providers. Indeed, in countries like India, many users already use multiple SIM cards, allowing them access to multiple providers.

Oligopoly pricing in wireless networks will also be heavily influenced by the Internet of things' needs for wireless connectivity. As these devices proliferate, with unique traffic patterns that are distinct from those of user requests on traditional cellular and WiFi networks, they will likely give rise to new pricing models that will require new analyses of wireless heterogeneity and oligopolistic competition in the wireless market.

Massive MIMO; Omnidirectional transmission

Definition

Omnidirectional transmission is used for cell-wide coverage for downlink common signals. It guarantees equal transmission power on each spatial direction.

Background

Massive multiple-input multiple-output (MIMO) is known to offer the advantages in increasing the spectrum and energy efficiency significantly, even with very low-complexity linear signal processing. It has received considerable interest from both academia and industry and is considered as one of the main techniques in the fifth generation (5G) of cellular systems (Marzetta 2010; Larsson et al. 2014).

In the context of massive MIMO, the transmission approaches for dedicated channels engaged in the exchange of user-specific data have been investigated intensively (Ngo et al. 2013; Adhikary et al. 2013; Sun et al. 2015; You et al. 2015; Lu et al. 2016). However, the transmission approaches for public channels have received little attention. Public channels

play crucial roles in cellular systems. Many essential common messages or services are provided to users by the base station (BS) through public channels, e.g., synchronization signals, reference signals, control signals, and multimedia broadcast/multicast services. Since public channels serve all the users in the cell rather than only certain active users, and not all the users' channel state information (CSI) can be obtained by the BS, the BS has to transmit common signals in public channels omnidirectionally to ensure cell-wide coverage. Hence the user in any spatial direction can have a reliable receiving signal-to-noise ratio (SNR).

Most omnidirectional transmission schemes developed for the conventional small-scale MIMO systems, such as single-antenna transmission or cyclic delay diversity (CDD), may be incompatible with massive MIMO. For example, consider single-antenna transmission, where one single antenna is selected from BS antennas to broadcast signals. In this case, the selected antenna must be equipped with a much more powerful and expensive power amplifier (PA) to ensure the same coverage area as all antennas are used for broadcasting signals. Nonetheless, this scheme would not work in a massive MIMO system. Since by using a large number of antennas, each antenna is made small with a much less powerful PA, and no antenna would be sufficiently powerful to serve as the single antenna mentioned above. Therefore, it is necessary to design an omnidirectional transmission approach for massive MIMO.

Omnidirectional Precoding-Based Transmission

It is known that without assuming any spatial structure for the channel, the length of the downlink pilot should not be less than the number of BS antennas. When considering massive MIMO where the number of BS antennas is very large, such a huge pilot overhead will lower the net spectrum efficiency significantly. In order to reduce the downlink pilot overhead, an omnidirectional precoding

(OP)-based transmission is proposed in Meng et al. (2016), where the high-dimension signal vector transmitted from the BS antenna array is composed by an $M \times N$ omnidirectional precoding (OP) matrix $\mathbf{W}$ and a low-dimensional signal vector, where M is the number of BS antennas. Owing to the OP matrix, the user does not need to estimate the actual channel of dimension M , but just needs to estimate the equivalent channel, i.e., the product of the actual channel and the OP matrix, of dimension N . In this case, the pilot length can be reduced to N .

Under the framework of OP-based transmission, the OP matrix should satisfy three basic requirements. Firstly, it should guarantee omnidirectional transmission, i.e., the transmission power on each spatial direction should be equal. Secondly, it should guarantee equal transmission power on each antenna to sufficiently utilize all the available PA capacities of BS antennas. Finally, it should maximize the ergodic rate for the Rayleigh independent and identically distributed (i.i.d.) channel. These three requirements can be, respectively, equivalent to three mathematical conditions:

$$\text{diag}(\mathbf{F}_M \mathbf{W} \mathbf{W}^H \mathbf{F}_M^H) = \frac{N}{M} \mathbf{1}_M \quad (1)$$

$$\text{diag}(\mathbf{W} \mathbf{W}^H) = \frac{N}{M} \mathbf{1}_M \quad (2)$$

$$\mathbf{W}^H \mathbf{W} = \mathbf{I}_N, \quad (3)$$

where $\mathbf{F}_M$, $\mathbf{1}_M$, and $\mathbf{I}_M$ denote the unitary M -point discrete Fourier transform (DFT) matrix, the $M \times 1$ column vector of all ones, and the $M \times M$ identity matrix, respectively, and $\text{diag}(\mathbf{A})$ denotes a column vector constituted by the main diagonal of a square matrix $\mathbf{A}$. Conditions (1), (2), and (3) mean that all the row vectors of $\mathbf{F}_M \mathbf{W}$ should have the same 2-norm, all the row vectors of $\mathbf{W}$ should have the same 2-norm, and $\mathbf{W}$ itself should be semi-unitary, respectively.

The OP matrix satisfying the above three conditions simultaneously can be designed with two different methods. The first one is based on Zadoff-Chu (ZC) sequences. A ZC sequence of length M has an elegant property that all

the M elements in this sequence have the same amplitude and all the M elements of the M -point DFT of this sequence still have the same amplitude (Chu 1972). By utilizing this property, the N columns of an $M \times N$ OP matrix $\mathbf{W}$ can be set as different cyclically shifted versions of a ZC sequence or different linearly modulated versions of a ZC sequence. In addition, when M is an integer multiple of N , $\mathbf{W}$ can also be constructed as

$$\mathbf{W} = \sqrt{\frac{N}{M}} \text{diag}(\mathbf{c})(\mathbf{1}_{M/N} \otimes \mathbf{I}_N) \quad (4)$$

where $\mathbf{c}$ denotes a ZC sequence of length M , $\text{diag}(\mathbf{c})$ denotes the diagonal matrix with $\mathbf{c}$ on the main diagonal, and $\otimes$ denotes the Kronecker product. The OP matrix in (4) not only satisfies conditions (1), (2), and (3) simultaneously but also has the following advantages: (1) it asymptotically maximizes the ergodic rate, maximizes the diversity order, and minimizes the outage probability in the large-scale array regime, not only for the i.i.d. channel but also for spatially correlated channels; (2) it preserves the peak-to-average power ratio (PAPR) of the transmitted signal after precoding (Meng et al. 2016). The second method for OP matrix design is based on Golay complementary sequences. A Golay complementary pair consists of two binary sequences with the same length and satisfying the complementary property that the respective aperiodic autocorrelation functions of these two sequences sum to a Kronecker delta function (Golay 1961). When utilizing Golay complementary sequences for OP matrix design, the number N of the columns of an $M \times N$ OP matrix $\mathbf{W}$ should be equal to or greater than two. This is different from the case with ZC sequence-based design, where N can be equal to one. When $N = 2$, the two columns of an $M \times N$ OP matrix $\mathbf{W}$ can be set as the two sequences in a Golay complementary pair directly. When $N > 2$ and N is even, the N columns of an $M \times N$ OP matrix $\mathbf{W}$ can be set as N -specific columns of an $M \times M$ Golay-Hadamard matrix (Meng et al. 2018). One advantage of Golay complementary sequence-based OP matrix design is that it guarantees equal

transmission power on any continuous spatial direction, while the ZC sequence-based design only guarantees equal transmission power on discrete spatial directions. In addition, since Golay complementary sequences are binary sequences, i.e., the elements take values in $\{\pm 1\}$, another advantage of Golay complementary sequence-based OP matrix design is that it will be suitable for radio-frequency (RF) precoding in the analog domain in millimeter wave systems (Xiao et al. 2017; Huang et al. 2018, to appear).

Conclusions

Omnidirectional transmission is used to guarantee cell-wide coverage for downlink common signals. To reduce the downlink pilot overhead in massive MIMO systems, the high-dimensional signal vector transmitted from the BS antenna array is composed by an OP matrix and a low-dimensional signal vector. The OP matrix has to satisfy three basic requirements, including omnidirectional coverage, equal transmission power on each antenna, and ergodic rate maximization for the Rayleigh i.i.d. channel. These three requirements are equivalent to three mathematical conditions correspondingly. There are two different methods to design such an OP matrix satisfying the three conditions simultaneously, based on ZC sequences and Golay complementary sequences, respectively.

Definition

The basic idea of opportunistic routing is to utilize all downstream nodes as potential forwarders and coordinate transmissions among forwarders. It has ability to overhear the transmitted packet and to coordinate among relaying nodes. In OR, the next-hop forwarder is decided after the sender broadcasts the data packets. Multiple downstream nodes in addition to that matching receiver will receive these packets and be potential forwarders. One of these potential forwarders, which is “closest” to the destination, will be selected to forward packets. The on-the-fly selection of the next-hop is the fundamental principle of opportunistic routing. Since multiple downstream nodes are potential next-hop forwarders, opportunistic routing can reduce the possibilities of reconstructing paths or retransmitting packets due to link breakage on a preselected path. Therefore, opportunistic routing benefits from the broadcast characteristic of wireless mediums to improve network performance.

Historical Background

A multi-hop wireless mesh network, wireless mesh in short, is a wireless data communication network in which end-to-end nodes are situated beyond direct radio transmission ranges. Intermediate nodes are required to forward data in order to enable communication between nodes that are far apart. Compared to single-hop wireless networks, such as Wi-Fi, Bluetooth, and cellular networks, multi-hop wireless networks can have extended communication ranges. Furthermore, they can provide coverage in hard-to-wire areas and improve the network throughput by short distance with reliable transmissions. The distinct features and critical design factors of multi-hop wireless networks also pose many problems. Routing is a central problem in wireless mesh. Routing algorithms will select a subset of intermediate nodes to create a path such that these intermediate nodes can forward packets from the source to the destination.

Most routing solutions are called traditional routing because they follow the Internet architecture of determining routes before forwarding data packets along the routes. Traditional routing preselects a fixed routing path before the source node starts transmissions. Each node in a route uses a preselected neighbor as the next-hop to forward data packets towards the destination. Once all next-hops have been selected, all packets transmitted between the source and the destination follow the same path. These routing solutions borrow ideas from the routing protocols for wire-line networks and do not adapt well to the dynamic wireless environment where transmission failure occur frequently. Wireless mesh networks are built on top of wireless links, and no longer have the constraints of point-to-point links prevalent in the Internet. In particular, wireless links are broadcast and subject to channel fading, which causes an uncertain number of nodes to receive a single transmission. In wireless networks, when a node transmits a data packet, multiple nodes can overhear the transmission, which can compensate for the transmissions failure to the preselected next-hop. However, traditional routing cannot utilize this broadcast nature of wireless mesh, because it dictates that all nodes without a matching receiver address should drop packets, and only the node that the routing module decides to be the next hop can keep packets for subsequent forwarding (Chakchouk 2015).

Foundations

The idea behind opportunistic routing is to utilize multiple nodes as potential forwarders and exploit multiple long but may unstable links concurrently, resulting in high expected progress per transmission (Biswas and Morris 2005). The routing for packet transmissions is not predetermined and can be updated for each packet of a flow. In opportunistic routing, a set of intermediate nodes between a source and a destination will be selected as potential forwarders, which are also called candidate nodes. Candidate selection algorithms decide the candidate nodes and determine the proper priority for each candidate.

Opportunistic Routing (OR), Fig. 1 An example of opportunistic routing

An effective routing metric will be used for the selection of candidate nodes and ordering nodes by their priorities (Zhong et al. 2006). The routing metric can show the ability of nodes to act as the next forwarder. The highest ability of a node may indicate that this node is “closest” to the destination. Initially, the typical routing metrics are from traditional routing protocols, for example, the expected number of transmissions or the hop count metric. After the selection of candidate nodes, opportunistic routing allows any potential forwarder to involve in packet transmissions according to the coordination algorithm, which is used to avoid duplicate transmissions and also guarantee reliable transmissions.

With a coordination algorithm, nodes that have received data packets from upstream nodes will decide whether to forward packets, discard packets, or wait for others’ transmissions. To coordinate transmissions, a node can send extra coordination messages or combine coordination information into data packets. The coordination message informs other nodes whether it has received packets or not; it is an accurate way to make coordination between nodes given that the coordination message is not lost. However, extra coordination messages require network resources and will slow down the transmission of data packets because data packets are usually sent out after a node receiving the coordination message. In addition to sending extra coordination messages, most opportunistic routing protocols combine coordination messages with data

packets instead. To increase the successful receiving possibility of coordination information, opportunistic routing protocols transmit a batch of data packets together in a round with a same coordination message. The coordination messages can be received if one of data packets in that batch is received (Boukerche and Darehshoorzadeh 2015).

We use the example in Fig. 1, inspired by Extremely Opportunistic Routing (ExOR) (Biswas and Morris 2005), to elaborate how opportunistic routing works. It presents the process of opportunistic routing and shows its advantages compared to traditional routing. In this example, the packet delivery probability is shown over the link. Traditional routing chooses the shortest path, $S-A-B-D$, to transmit packets. When S sends packets to node A , data packets are transmitted by broadcasting. Downstream nodes (B or D) may receive some packets. Neither node B nor D is selected as the next hop of the source; even though they receive some packets, these packets have to be retransmitted by node A . Therefore, the traditional routing scheme has many unnecessary transmissions and wastes network resources. By contrast, opportunistic routing can increase the performance of packet transmissions by taking advantage of the broadcast nature of wireless media, specifically long-distance transmissions. ExOR uses the Expected Transmission Count (ETX (Couto et al. 2003)) as the routing metric, which calculates the average number of transmission that a packet

required to be received by the destination. The ETX value of a corresponding link is the inverse of the packet delivery probability of that link. The ETX value on a path can be derived by adding up all ETX values of each link on this path. The definition of an ETX value of a node is the minimum ETX value of paths from this node to the destination. The intermediate nodes with an ETX value smaller than that of the source will be selected as candidate nodes. In this example, the candidate nodes are $\{A, B, F, D\}$. Each intermediate node will be assigned a priority based on its ETX value. Nodes with a small ETX value will be assigned a high priority. Therefore, the order of the priority is $D > B > A > F$. After the source node sends packets, multiple candidate nodes are involved in receiving and forwarding packets. In ExOR, the high priority node will forward the received packet first, e.g., if both nodes A and B receive a packet from the source, node B will forward this packet first. When node A overhears node B 's transmission, it discards the same packet since node B already forwards this packet to downstream nodes. If node D receives this packet from the source, neither node A or B will forward the same packet.

Therefore, opportunistic routing is likely to increase total network capacity as well as individual connection throughput. It transmits each packet fewer times than traditional routing, which should cause less interference for other users of the network and of the same spectrum.

Key Applications

Opportunistic routing is fundamental in all wireless mesh networks or ad hoc networks. It has increased the efficiency, throughput, and reliability by utilizing the broadcasting nature of the wireless medium.

Definition

Underwater wireless sensor networks (UWSNs) are normally used to collect data from the acoustic environment and transfer the data from the sensor devices to the sonobuoys on the surface. In UWSNs, opportunistic routing (OR) (Larsson 2001) is an ideal routing paradigm to reduce energy consumption and increase path reliability.

Historical Background

Knowing and investigating the ocean is important to people in order to sustain human life. The wireless communication-enabled sensor devices can be deployed to monitor and observe aquatic information. Due to the ocean environment, the sensor nodes are mobile as freely floating by the ocean current where the nodes are connected ad hoc to form a dynamic wireless network.

Similar to other types of wireless sensor networks, most sensor nodes in UWSNs are also energy-constrained; thereby we can refer UWSNs as a special type of WSN. However, compared to traditional WSNs, UWSNs could suffer low path reliability and energy problem because of the rapid attenuation of radio signals and the dynamic movement of sensor nodes.

Also, because traditional wireless routing protocols require regular updates and maintenance in order to establish the routing paths where such routing paradigms could demand high energy consumption, this leads that the routing design of traditional routing protocols could not work efficiently for UWSNs. We can see from this point, although UWSNs and traditional wireless sensor networks share many similarities, there are still quite many distinguishing characteristics of UWSNs such as float with current, energy constrained, and narrow bandwidth.

Compared to traditional routing where packets are transmitted along predetermined paths, OR uses a prioritization metric (routing metric) to select a set of candidates as potential forwarders (usually called candidate set, CS) in OR. According to some routing criteria or priority (determines the ability to reach the destination with lower forwarding cost), the group of nodes then coordinate among each other and decide one node with the highest priority from this group to be next forwarder. This forwarder will further broadcast the data message (packet) to its neighbor to repeat the above procedure until the destination receiver receives the message. As described above, OR shows its distinguishing characteristics to work in unreliable environments. It provides efficient routing paths with the increased possibility of accomplishing the transmissions.

More, by creating strong virtual links and minimizing the number of retransmissions, the path reliability and the energy consumption are both reduced. Therefore, OR is a perfect paradigm to overcome the limits of bandwidths, channels, and energy in UWSNs.

In UWSNs, energy efficiency is the primary challenging issue mostly due to the attenuation of frequent changing topology and acoustic radio signal in the underwater environment. Hence, large variable latency and serious path loss (could be the temporary loss of paths), as well as low bandwidth, could be experienced under such condition. Further, due to the unreliable path, packet retransmission can occur with higher energy consumption. Therefore, as the energy is one of the most important issues in UWSNs, the design of the routing scheme should consider how to enable energy-efficient routing selection or packet forwarding. Besides, since sensor nodes float freely with the ocean current movement, the topology of UWSN could be highly dynamic. Forwarding the packet to a relay node with geographical advantages is essential to reducing latency. Therefore, the design of geographic-based routing schemes is to select a forwarder node in a better position (e.g., closer to the destination) in order to shorten the delay during the packet transmission.

Therefore, in the following paragraphs, we introduce how OR works in detail. As shown in Fig. 1, an OR paradigm consists of three main components, routing metrics, candidate selection, and candidate coordination (Darehshoorzadeh and Boukerche 2015; Coutinho et al. 2016). Each component is presented as follows.

- (a) **Routing Metrics:** Generally, in networking, routing metrics is referred to as the method to determine whether a node or a link is better than another or not. In UWSNs, the metric could be either about the local information or about the global information. For global (or end-to-end) metric (Darehshoorzadeh and Boukerche 2015), the information of the whole network should be collected to judge the quality of a next forwarder in CS. In contrast, for local metric, only local information including the information of

CS and neighbors of CS is considered to select the next-hop forwarder. It is obvious that the global metric could help to select a better forwarder than local metric. However, while using a global metric, great overhead with high energy consumption could be created while gathering the information of the entire network. Besides, in UWSNs, it is not feasible to obtain information of the entire network which is very costly.

- (b) **Candidate Selection:** In OR, a packet is sent to the neighbors (CS) of the current sender/forwarder. Based on the information of the network (i.e., routing metrics), the nodes in the CS need to select the optimal candidate as the next forwarder(s) to forward the packet toward the destination node. One or multiple nodes from the CS could be chosen as a forwarder(s), whereas the overhead may be high if multiple forwarders are used. The candidate selection mechanisms can be divided into two main categories, topology-based and geographic-based. The global routing metrics are normally applied in the topology-based candidate selection to provide the information of network topology, while the local routing metrics are used in the geographic-based candidate selection to find the forwarder in a better position for relaying packet. As topology-based candidate selection uses information of whole network, the selection of the candidates is more complex than using the local information.
- (c) **Candidate Coordinate:** Once the packets are received by a CS, the nodes of the CS should coordinate and collaborate with each other in order to decide which node out of this CS must continue to forward the packet and which nodes should discard the packet after this. The procedure of coordinating among candidate nodes is referred as candidate coordination.

As depicted in Fig. 1, in UWSNs, the OR protocols can be classified into two main categories, geographic-based and pressure-based (Darehshoorzadeh and Boukerche 2015) where

Opportunistic Routing in Underwater Sensor Networks, Fig. 1 The procedures and classification of OR

position information and pressure (depth of sensor node) information are used for these two categories for candidate selection, respectively. The representative geographic-based routing schemes are vector-based forwarding (VBF) (Xie et al. 2006), hop-by-hop VBF, and geographic and opportunistic routing with depth adjustment-based topology control for communication recovery (GEDAR) (Coutinho et al. 2014), while the representative pressure-based routing schemes are hydraulic pressure-based anycast routing (HydroCAST) (Lee et al. 2010), void-aware pressure routing (VAPR) (Noh et al. 2013), and E-PULRP (Gopi et al. 2010).

Key Applications

UWSN is a promising technology which can be applied in many underwater (ocean, rivers, and lakes) scenarios, e.g., ocean data collection, wild benthos studies, marine climate observation, off-shore exploration, military tactical surveillance, and offshore exploration. In particular, opportunistic routing could provide a pathway with less energy consumption and enhanced reliable communication to support these scenarios. The key applications of UWSNs (Felemban et al. 2015) are presented below.

- (a) **Environment Monitoring:** The efficient routing of UWSN could be applied to monitor the

water quality, habitat as well as the offshore underwater exploration, etc. For example, the application based on UWSN has been developed to monitor the water quality of rivers in India and China (Menon et al. 2012; He and Zhang 2012). The UWSN-based European-funded project, ACMENet, is constructed to collect environment of the living environment of marine life (Acar and Adams 2006). Other work (Lloret et al. 2011; Lpez et al. 2009) also employs UWSNs to the applications of UWSNs provide a cheap and real-time monitor of various underwater species. Besides, UWSNs have been deployed to monitor and investigate the underwater natural resources and infrastructures such as marine optical cables, marine oil field, marine gas pipelines, etc. as an alternate of wired sensors (Heidemmann et al. 2006; Srinivas et al. 2012; Jawhar et al. 2007; Saeed et al. 2014).

- (b) Disaster Monitoring: UWSNs have been applied to efficiently collect the disaster data and prevent disasters in the aftermath disaster scenario. There is a multitude of UWSN applications including underwater earthquake, tsunamis (Kumar et al. 2012), flood (Pasi and Bhawe 2015), oil spillage (Khan and Jenkins 2008), volcanic eruptions, etc. For example, UWSN is deployed to detect and analyze ocean pollution, oil spillage, and gas pipeline (Khan and Jenkins 2008). Also, with the application of UWSNs, the flood indicators such as water level and temperatures could be monitored in real time (Marin-Perez et al. 2012).
- (c) Military: As an economical solution, UWSNs can be deployed to clear underwater mines and detect naval submarines as well as for near- or offshore monitoring and surveillance, using autonomous underwater vehicle (AUV). For example, sensors have been deployed on the AUV or located on the side of AUV to detect and analyze the underwater mines (Rao et al. 2009). With the advanced sensing ability, in the military, another instance of application of UWSNs is to localize the target submarines (Hamilton et al. 2010).

PAPR Reduction in OFDM Systems

Hao Li
Department of Electrical and Computer Engineering, The University of Western Ontario, London, ON, Canada

Definitions

Peak-to-average power ratio (PAPR) reduction is a technique used to reduce the peak-to-average power ratio of transmitted signals so that the power amplifier at the transmitter is not driven into saturation by high signal peaks.

Historical Background

The development of PAPR reduction techniques dates back to 1970s, when complementary sequences were utilized to minimize the peak factor of multitone signals (Schroeder 1970; Greenstein and Fitzgerald 1981; Boyd 1986). This was the initial coding strategy to reduce the PAPR of multi-carrier signals. Along with the popularity and commercial use of orthogonal frequency division multiplexing (OFDM) in 1990s, many efforts have been made to overcome the high-PAPR challenge in OFDM transmission. Various methods of PAPR reduction in OFDM systems, as well as their subsequent improvement schemes, were proposed. In 1994, a block coding scheme was proposed (Jones et al. 1994), by adding a Simple Odd Parity Code (SOBC) at the end of each three data bits to reduce the PAPR. The simplest and most widely used clipping technique was introduced by O'Neill and Lopes in 1995 (O'Neill and Lopes 1995), which basically clipped the parts of signals that were outside a predetermined region. In 1996, the coding strategy was further developed to have both PAPR reduction and error correction capabilities (van Nee 1996). Within the same year, a selected mapping (SLM) method (Bäumel et al. 1996) and interleaving method (Eetvelt et al. 1996) were published, by exploiting the multi-carrier attribute of OFDM signals. A few months later, a partial transmit sequence (PTS) method that optimally rotated signal subblocks was proposed (Müller and Huber

1997). In 1998, a peak windowing technique that could suppress out-of-band radiation while reducing the peak signal was introduced (van Nee and de Wild 1998). Another three typical PAPR reduction methods for OFDM, including nonlinear companding transform (Wang et al. 1999), tone reservation (TR), and tone injection (TI) (Tellado 1999), were proposed in 1999.

Modifications of these key PAPR reduction strategies are continuously investigated till today, in order to achieve a trade-off between the capacity of PAPR reduction and the transmission power, data rate loss, implementation complexity, and bit-error-rate (BER) performance. In recent years, some hybrid methods were also proposed by hybridizing two or more PAPR reduction schemes (Sandoval et al. 2017).

PAPR of OFDM Signals

OFDM has been widely adopted in modern communication systems. For an OFDM signal with N subcarriers, it can be mathematically expressed as

$$x(t) = \sum_{k=0}^{N-1} X(k) e^{j2\pi f_k t}, \quad 0 \leq t \leq T, \quad (1)$$

where $X(k)$ is the data symbol transmitted on the k th subcarrier and T is the duration of one OFDM signal. $f_k = k\Delta f$ is the frequency of the k th subcarrier, where Δf is the subcarrier spacing and $T\Delta f = 1$.

Normally, data symbols to be transmitted on the subcarriers, i.e., $X(k)$, $k = 0, 1, \dots, N-1$, are independent, identically distributed (i.i.d.) random variables. Based on the central limit theorem, when N is considerably large, the resulting signal $x(t)$ approaches a complex Gaussian process. A small percentage of signal points will take very large magnitudes, resulting into a high PAPR. Technically, the PAPR of a time-domain OFDM signal $x(t)$ is defined as the ratio between its maximum instantaneous power and the average power, which can be written as

$$\text{PAPR}[x(t)] = \frac{\max_{0 \leq t \leq T} |x(t)|^2}{\frac{1}{T} \int_0^T |x(t)|^2 dt}. \quad (2)$$

In the case that a time-domain OFDM signal $x(t)$ is obtained by L -times oversampling, the PAPR computed from the L -times oversampled signal samples can be defined as

$$\text{PAPR}[x(n)] = \frac{\max_{0 \leq n \leq NL-1} |x(n)|^2}{\frac{1}{NL} \sum_{n=0}^{NL-1} |x(n)|^2}. \quad (3)$$

A large PAPR would drive power amplifiers at the transmitter into saturation, causing in-band signal distortion and out-of-band radiation. The nonlinear distortions would increase the BER and induce a serious degradation in system performance.

Key PAPR Reduction Methods in OFDM Systems

Various approaches have been proposed to reduce the PAPR in OFDM systems. In general, these methods can be classified into three categories: signal distortion techniques, signal scrambling techniques, and hybrid techniques.

Signal Distortion Techniques

Clipping and Filtering Clipping is a method to reduce the signal peaks to a desired level. If the signal exceeds a predetermined clipping level A , a clipper would limit the signal envelope to the clipping level. Otherwise, the clipper passes the signal without change (O'Neill and Lopes 1995). The output signal of the clipping operation, $\hat{x}(n)$, can be given by

$$\hat{x}(n) = \begin{cases} x(n), & |x(n)| \leq A \\ Ae^{j\angle[x(n)]}, & |x(n)| > A \end{cases}, \quad (4)$$

where $\angle[x(n)]$ represents the phase of $x(n)$. Clipping is a nonlinear process that leads to both in-band and out-of-band distortions. Filtering can

thus be employed after clipping to reduce out-of-band radiation. However, filtering may also cause peak regrowth so that the signal after clipping and filtering could exceed the clipping level again at some points. To reduce overall peak regrowth, an iterative clipping-and-filtering operation can be used at the cost of additional computational complexity (Li and Cimini 1998).

Peak Windowing Peak windowing method attenuates signal peaks in a much smoother way compared to the hard clipping, resulting in reduced distortion. In this method, the original OFDM signal is multiplied by a shaped window such as Gaussian, Kaiser, Hamming, or cosine filters (van Nee and de Wild 1998). As these windows have a narrow impulse response in the time domain and approximately rectangular spectrum in the frequency domain, peak windowing can suppress out-of-band radiation while reducing the signal peaks.

Companding Transform Companding transform is a method to nonlinearly scale the OFDM signal by suppressing signal points with large amplitudes and expanding signal points with small amplitudes (Wang et al. 1999). At the receiver, the original signal is recovered from the companded signal via the decompanding process. Different companding algorithms can be utilized, including linear symmetrical transform (LST), linear asymmetrical transform (LAST), nonlinear symmetrical transform (NLST), and nonlinear asymmetrical transform (NLAST) (Rahmatallah and Mohan 2013). For instance, the LST companding algorithm can be written as

$$\hat{x}(n) = ax(n) + b, \quad (5)$$

where $0 < a < 1$ is the slop parameter and $b > 0$ is the bias parameter. Companding transform is able to reduce PAPR in OFDM systems without any side information. However, it could increase the quantization error, resulting into a higher BER.

Signal Scrambling Techniques

Coding The principle of coding method is to reduce the occurrence probability of the same phase at OFDM subcarriers, so as to reduce the occurrence of very high peaks. Block coding, convolutional coding, and concatenate coding schemes can all be employed to reduce the PAPR (Jones et al. 1994; van Nee 1996). The main disadvantage of the coding method is the high computational complexity to search for adequate code words, particularly when the number of subcarriers is large. Also, the PAPR reduction is at the cost of coding rate loss.

SLM In SLM method, an input data vector of N symbols is multiplied by U phase sequences $\mathbf{P}^u = [P_0^u, P_1^u, \dots, P_N^u]$, $1 \leq u \leq U$ to generate U alternative symbol sequences that represents the same information as the original data block. Inverse discrete Fourier transform (IDFT) is performed for each of the U alternative symbol sequences, and then the one with the lowest PAPR is selected for transmission (Bäumel et al. 1996). In order to recover the original input data vector, information about the selected phase sequence has to be transmitted to the receiver as side information. Also, its computational complexity is quite high due to the operation of U IDFTs.

PTS In PTS method, an input data vector of N symbols is partitioned into M disjoint subblocks. The subcarriers in each subblock are weighted by a phase factor designated for that subblock. The M phase factors are selected such that the PAPR of the combined OFDM signal is minimized (Müller and Huber 1997). Similar to the SLM method, the side information, i.e., the selected phase factors, must be transmitted to the receiver to recover the original data vector. Also, the search complexity of an adequate set of phase factors increases exponentially with the number of subblocks.

Interleaving The interleaving method is similar to the SLM scheme. V interleavers that per-

mute or reorder a block of symbols in respective ways are applied on the input data vector to produce V different permuted data vectors. IDFT is performed on each one of the V permutations separately, and the one with the lowest PAPR is chosen for transmission (Eetvelt et al. 1996). To recover the original data vector, the receiver needs to be informed which interleaver is used at the transmitter. Its computational complexity is also high due to the calculation of V IDFTs.

TR The TR method is to reserve a small set of subcarriers for transmitting PAPR reduction signals instead of data transmission. Let $\mathcal{R}_c$ denote the set of PAPR reduction subcarriers and $\mathcal{R}_d$ denote the set of data subcarriers. The input data vector following the TR method turns to

$$\hat{X}(k) = X(k) + C(k) = \begin{cases} C(k), & k \in \mathcal{R}_c \\ X(k), & k \in \mathcal{R}_d \end{cases}, \quad (6)$$

where $C(k)$ denote the PAPR reduction signals, which are generated to minimize the maximum peak value of $\text{IDFT}(\hat{X}(k))$ through a convex optimization. In TR scheme, the receiver only needs to know the position of the PAPR reduction subcarriers but not the actual PAPR reduction signals $C(k)$. However, the subcarriers reserved for the PAPR reduction cause a data rate decrease. Moreover, additional processing power is required at the transmitter to generate the PAPR reduction signals.

TI The basic idea of TI method is to increase the constellation size of symbols at OFDM subcarriers, so that each of the points in the original constellation can be mapped into several equivalent points in the expanded constellation, prior to the IDFT processing. The extra degrees of freedom, i.e., each symbol can be mapped into one of the several equivalent constellation points, are exploited for PAPR reduction. For a square QAM constellation of size M and minimum distance between constellation points d , the QAM symbol $X(k)$ can be mapped to the expanded constellation as

$$\hat{X}(k) = X(k) + p_k D + q_k D, \quad (7)$$

where $D = \rho d \sqrt{M}$, $\rho \geq 1$ represents the spacing between the original point in the original constellation and its equivalent points in the expanded constellation. p_k and q_k are integer numbers used to change the real and imaginary parts of $X(k)$, which are selected to reduce the PAPR. The amount of PAPR reduction depends on the value of ρ and the number of expanded symbols in a data block. It is noteworthy that the injected signals in the TI method have an increased energy, which would increase the average transmit power.

Hybrid Techniques

Hybrid techniques combine two or more methods for PAPR reduction. The hybridization can have the advantages of the combined methods, albeit with slight increases in complexity. A few studies have validated the combination of coding-based PAPR reduction method with clipping, SLM, and PTS schemes. These combined methods can achieve significant PAPR reduction with a small data rate loss, while the coding technique presents good error control properties (Sandoval et al. 2017).

Key Applications

PAPR reduction is fundamental in the implementation of OFDM systems, particularly when the number of subcarriers is large.

[Channel estimation](#); [Parameter estimation](#)

Definitions

The deployment of the WSN can form arbitrary topology geometry. The parameter estimation can be estimated based on the received data of the sensors in WSN.

Historical Background

Wireless sensor network (WSN) is a distributed sensing network with hundreds or thousands of sensors that sense and examine the outside world. The sensors in the WSN communicate in a wireless way, so the network settings are flexible. The location of sensors can be changed at any time, and the Internet can be connected with the WSN in a wired or wireless manner. A multi-hop self-organizing network formed by wireless communication. The WSN can be deployed in different areas to monitor the targets of interest (Wan et al. 2015). The topology of the WSN can be arbitrary. When the sensors of WSN are mounted on the surface of complex carrier, they construct a conformal array (Josefsson and Persson 2006). Compared with traditional array, the conformal array has some characteristics. First, due to the irregular structure of the carrier, the sensors of WSN conforming to the surface of the carrier have directionality, i.e., it has different pattern functions and has different responses to incident signals of different directions. Second,

the curvature of the complex carrier surface generally has a radius, and the maximum radiation direction of each sensor is almost different. Third, when the signal is impinging on the surface of the carrier from certain directions, some of the sensors cannot receive the signal, or the received signal is weak due to the occlusion effect of the carrier. These characteristics mentioned above have brought unprecedented challenges to the parameter estimation of WSN. Thus, the parameter estimation for targets of interest based on WSN is an important problem to solve due to the arbitrary topology geometry of the WSN.

The Signal Model with Arbitrary Topology Geometry

As shown in Fig. 1, a WSN is mounted on the surface of an arbitrarily shaped carrier. Assume that there are M sensors on the surface of carrier. In global coordinate system, the coordinate of each sensor can be expressed as (x_m, y_m, z_m) , $m = 1, 2, \dots, M$. The origin of the global coordinate

system is the position of sensor $\mathbf{p}_1$, and the origins of the local coordinate systems are the positions of sensor $\mathbf{p}_m$. For the identical signal, the azimuth angle and elevation angle are different in global and local coordinate systems. This is different with the traditional array, e.g., uniform linear array (ULA). For the traditional array, there is only one azimuth angle and elevation angle corresponding to the identical signal.

The signals impinging on the arbitrary array consisting of M sensors are narrowband farfield signals, the direction vector $\mathbf{u}$ with frequency f can be expressed as $\mathbf{u} = [-\sin(\theta)\cos(\varphi) \quad -\sin(\theta)\sin(\varphi) \quad -\cos(\theta)]^T$, where θ and φ stand for the elevation angle and azimuth angle, respectively. “T” stands for the transpose of a vector or a matrix.

The Signal Model with Conformal Array

The array manifold of conformal arrays is modeled by geometric algebra in Zou et al.

Parameter Estimation Exploiting WSNs with Arbitrary Topology Geometry, Fig. 1 The structure of the conformal array constructed by WSN

(2011), but the geometric algebra method is too abstract when analyzing the coordinate system rotation, which makes it difficult to establish an intuitive impression of this method. In this paper, the Euler rotation transformation method proposed in Wang et al. (2008) and Wan et al. (2014) is used to realize the conversion between the global coordinate system and the local coordinate system of the sensor.

Consider r signals from different directions (θ_i, φ_i) , $i = 1, 2, \dots, r$ impinge on the conformal array consisting of M sensors, where θ_i and φ_i are the elevation angle and azimuth angle of the i th incident signal in global coordinate system, respectively. The snapshot data matrix received by the conformal array can be expressed as $\mathbf{X}(t) = \mathbf{A}(\theta, \varphi)\mathbf{S}(t) + \mathbf{N}(t)$, where $\mathbf{X}(t)$ is the $M \times 1$ snapshot data vector, $\mathbf{S}(t)$ is the $r \times 1$ signal vector, $\mathbf{N}(t)$ is $M \times 1$ noise vector, and $\mathbf{A}(\theta, \varphi)$ is $M \times r$ manifold matrix of conformal array, which can be expressed as $\mathbf{A}(\theta, \varphi) = [\mathbf{a}(\theta_1, \varphi_1), \mathbf{a}(\theta_2, \varphi_2), \dots, \mathbf{a}(\theta_r, \varphi_r)]$, where $\mathbf{a}(\theta_i, \varphi_i)$ is the steering vector of the i th signal expressed as $\mathbf{a}(\theta_i, \varphi_i) = [g_1(\theta_i, \varphi_i) \exp(-j2\pi \frac{\mathbf{p}_1 \cdot \mathbf{u}}{\lambda}), g_2(\theta_i, \varphi_i) \exp(-j2\pi \frac{\mathbf{p}_2 \cdot \mathbf{u}}{\lambda}), \dots, g_M(\theta_i, \varphi_i) \exp(-j2\pi \frac{\mathbf{p}_M \cdot \mathbf{u}}{\lambda})]^T$, $\mathbf{p}_m = (x_m, y_m, z_m)$, $m = 1, 2, \dots, M$, where $g_m(\theta_i, \varphi_i)$ stands for the direction pattern of the m th sensor for the direction (θ_i, φ_i) in the global coordinate system, “ $\cdot$ ” stand for the Hadamard product, $\mathbf{p}_m$ stands for the position vector of the m th sensor. For the traditional linear array, the sensors in the WSN have the identical direction pattern. Thus $g_m(\theta_i, \varphi_i)$ is normalized as 1. However, for the conformal array, the sensors in the WSN have different direction patterns due to the curvature of the complex carrier surface. The different direction patterns bring new challenges for parameter estimation. The accurate modelling of the direction pattern of $g_m(\theta_i, \varphi_i)$ should be taken into consideration, and the direction pattern of the sensor should be designed in its local coordinate system. Thus a key problem for the modelling of the steering vector of the conformal array is the direction pattern transformation between the local coordinate system and the global coordinate system.

For the global coordinate system and the m local coordinate system, we can, respectively, obtain $x = \rho \sin \theta \cos \varphi$, $y = \rho \sin \theta \sin \varphi$, $z = \rho \cos \theta$ and $x_m = \rho_m \sin \theta_m \cos \varphi_m$, $y_m = \rho_m \sin \theta_m \sin \varphi_m$, $z_m = \rho_m \cos \theta_m$.

We only know the directions of the impinging signals, and we set $\rho = \rho_m = 1$, where θ_m and φ_m stand for the elevation angle and azimuth angle in the m th local coordinate system of the impinging signal.

Then the conversion of each component from the global Cartesian coordinate system to the m th local Cartesian coordinate system should be completed based on three Euler rotation transformations. Each transformation corresponds to a Euler rotation matrix, i.e., the conversion from the global Cartesian coordinate system to the m th local Cartesian coordinate system can be realized by using three orthogonal transformation matrices, $\mathbf{R}_X$, $\mathbf{R}_Y$, and $\mathbf{R}_Z$, where $\mathbf{R}_X$ is expressed as $R_X = [1, 0, 0; 0, \cos \alpha_X, -\sin \alpha_X; 0, \sin \alpha_X, \cos \alpha_X]$. It indicates that the X axis of the global coordinate system is the rotation axis, $-\pi \leq \alpha_X \leq \pi$. Clockwise is positive during the rotation and negative counterclockwise.

$\mathbf{R}_Y$ is expressed as $R_Y = [1, 0, 0; 0, \cos \alpha_Y, -\sin \alpha_Y; 0, \sin \alpha_Y, \cos \alpha_Y]$. It indicates that the Y axis of the global coordinate system is the rotation axis, $-\pi \leq \alpha_Y \leq \pi$. Based on the right-handed spiral rule, we face the negative direction of the X axis and rotate on the YOZ plane. The rotation angle α_X in the equation can be expressed as the angle between the Y axis (or Z axis) of the new coordinate system and the Y axis (or Z axis) of the original coordinate system.

$\mathbf{R}_Z$ is expressed as $R_Z = [1, 0, 0; 0, \cos \alpha_Z, -\sin \alpha_Z; 0, \sin \alpha_Z, \cos \alpha_Z]$. It indicates that the Z axis of the global coordinate system is the rotation axis, $-\pi \leq \alpha_Z \leq \pi$. Based on the right-handed spiral rule, we face the negative direction of the Z axis and rotate on the XOY plane. The rotation angle α_Z in the equation can be expressed as the angle between the X axis (or Y axis) of the new coordinate system and the X axis (or Y axis) of the original coordinate system.

Therefore, the conversion relationship between the global Cartesian coordinate system and the m th local Cartesian coordinate system can be obtained $[x_m; y_m; z_m] = \mathbf{R}_X \mathbf{R}_Y \mathbf{R}_Z [x; y; z]$.

The design of the pattern of the sensor is usually based on the local coordinate system of the sensor itself. Therefore, it is necessary to obtain the elevation angle and azimuth angle of the impinging signal in the local coordinate system. The conversion between the spherical coordinate system and the Cartesian coordinate system can be expressed as $\theta_m = \arccos z_m$, $\varphi_m = \arctan(\frac{y_m}{x_m})$. The transform between global Cartesian coordinate system and the local Cartesian coordinate system is achieved.

Conclusions

In this entry, we introduce a coordinate rotation transformation method for conformal array consisting of sensors in the WSN. Based on this method, the WSN with arbitrary topology configuration can be used for the parameter estimation, e.g., direction of arrival, etc.

Future Directions

In the future, we will design novel model for conformal array and develop parameter estimation algorithms for WSN with arbitrary.

Key Application

The parameter estimation with arbitrary topology geometry can be used for detecting and tracking the moving targets. In addition, the conformal array can be mounted on the aircraft to reduce the air resistance. This structure has the smallest radar cross section, and the aircraft is hard to detected.

Path Loss and Interference Analysis for a Random Two-Hop Relay Link

Ruonan Zhang¹ and Jianping Pan²

¹Northwestern Polytechnical University, Shaanxi, China

²University of Victoria, Victoria, BC, Canada

Technical Background

In relay communications, signals from a source station (SS) are relayed to a destination station (DS) by one or more relay stations (RSs), as shown in Fig. 1. In radio propagation, signal power decays with the increase of transmission distance superlinearly with a certain exponent (3GPP 2017; Wang et al. 2017). By reducing the propagation distance in each hop through a relay link, the total transmission power is reduced, and each hop can achieve a higher data rate. Consequently, the relay communication leads to a higher spectrum and power efficiency and end-to-end throughput. Meanwhile, the coverage range of a station is increased significantly. The cooperative communications in cellular networks and the peer-to-peer communications in ad hoc wireless networks are both based on the relay communications and have attracted considerable

research effort in recent years (Sheng et al. 2011; Zhang et al. 2016; Qin et al. 2015) (Table 1).

A relay link also generates interference to other stations in a wireless network, as illustrated in Fig. 1. The interference is herein the signals transmitted from an RS and received by a non-destination station. The station under interference is referred to as an *interfered station (IS)*. Suppose that the RSs employ the amplify-and-forward (AF) mode by which each RS amplifies the received radio signals and directly transmits them without decoding and encoding. The AF scheme is easy to implement in practice when compared to the others such as the decode and forward (DF) and cooperative coding (CC) schemes. Therefore, the interference for AF relay scheme is discussed in this entry.

According to Fig. 1, let $P_{t,s}$ and $P_{t,h}$ denote the transmission power at the SS and RS (helper), respectively, and $P_{r,h}$ and $P_{r,i}$ denote the received power at the RS and IS, respectively. Let G_s , G_h , and G_i be the antenna gains at the SS, RS, and IS, respectively. Suppose that the distances from the SS to the RS and from the RS to the IS are $D_{s,h}$ and $D_{h,i}$, respectively. Based on the close-in (CI) free space reference distance model, the path loss (PL) of the first hop (from the SS to the RS), denoted by $L_{s,h}$, is

$$L_{s,h} = \frac{P_{t,s}}{P_{r,h}} = \frac{1}{G_s G_h} \left(\frac{4\pi d_0}{\lambda} \right)^2 \left(\frac{D_{s,h}}{d_0} \right)^\alpha, \quad (1)$$

Path Loss and Interference Analysis for a Random Two-Hop Relay Link, Fig. 1 Two-hop relay communications and interference in a wireless network. (a) Cellular network. (b) Ad hoc network

Path Loss and Interference Analysis for a Random Two-Hop Relay Link, Table 1 Definitions in this article

Interference	Addition of unwanted signals which modify or disrupt a useful signal
Source station	A station that generates and sends original information
Destination station	A station designated as the receiver of information
Relay station	A station that receives and passes along signals or information to another station
Interfered station	A station that is interfered by the signals from other stations
Cellular network	A wireless communication network where the access service is organized in cells
Ad hoc network	A decentralized wireless network where each node may forward data for other nodes
Path loss	Attenuation of power density when a radio signal propagates over a distance
Antenna gain	Amplification of signal power by an antenna at a specific direction

where λ is the signal wavelength and α is the path loss exponent (PLE). The d_0 in (1) is the reference distance and usually set to 1 ~ 10 meters for indoor and 1 kilometer for outdoor scenarios. The PL between the RS and IS, denoted by $L_{h,i}$, is defined similarly by (1) with the antenna gains and propagation distance between the RS and IS accordingly.

The average received power is mainly determined by the PL of each hop, with shadowing and fading which are often distance independent. Suppose that the amplification gain of the RS is A_{rel} in the AF relaying. The interference power at the IS is

$$P_{r,i} = \frac{P_{t,h}}{L_{h,i}} = \frac{A_{rel} P_{t,s}}{L_{s,h} L_{h,i}} = \beta (D_{s,h} D_{h,i})^{-\alpha}, \quad (2)$$

where

$$\beta = A_{rel} G_s G_h^2 G_i P_{t,s} d_0^{2\alpha} \left(\frac{\lambda}{4\pi d_0} \right)^4. \quad (3)$$

The system parameters in (2), such as the transmission power, amplification gain, and antenna gains, are usually fixed by the hardware design and implementation. Thus, the term β is a constant and the interference power at the IS, $P_{r,i}$, is proportional to the term $(D_{s,h} D_{h,i})^{-\alpha}$. Therefore, the distribution of the product of the two transmission distances, $D_{s,h} D_{h,i}$, determines the statistics of the interference over the two-hop link. However, the RS is usually randomly located in a wireless network, depending on the available resources, signal relay efficiency, and motivation to help other stations (Zhuang and Zhou 2013). Thus the

distances $D_{s,h}$ and $D_{h,i}$ are stochastic and dependent. Let $F_{D_{s,h} D_{h,i}}(d)$ and $f_{D_{s,h} D_{h,i}}(d)$ denote the CDF and PDF of the distance product, respectively. The CDF of the interference power is

$$\begin{aligned} F_{P_{r,i}}(p) &= \Pr \{ P_{r,i} < p \} = \Pr \{ \beta (D_{s,h} D_{h,i})^{-\alpha} < p \} \\ &= \Pr \left\{ (D_{s,h} D_{h,i}) > \left(\frac{\beta}{p} \right)^{\frac{1}{\alpha}} \right\} \\ &= 1 - F_{D_{s,h} D_{h,i}} \left[\left(\frac{\beta}{p} \right)^{\frac{1}{\alpha}} \right]. \end{aligned} \quad (4)$$

By taking the derivative of $F_{P_{r,i}}(p)$ with respect to p , the PDF of the interference power can be obtained as

$$f_{P_{r,i}}(p) = \frac{dF_{P_{r,i}}(p)}{dp} = \frac{\beta^{\frac{1}{\alpha}}}{\alpha p^{\frac{1}{\alpha}+1}} f_{D_{s,h} D_{h,i}}(d). \quad (5)$$

With the distributions of the received signal and interference strength, signal-to-interference-plus-noise ratio (SINR), link capacity, and outage probability can be obtained accordingly. Please note that although the CI model is adopted to derive the interference power from (1) to (3) here, other PL models can be used, such as the floating-intercept (FI) model. Because the PL is generally increased superlinearly with the distance powered to the PLE, the interference power is proportional to $(D_{s,h} D_{h,i})^{-\alpha}$. Thus the results in (4) and (5) and the approach are applicable to

other PL models, and the coefficient β is changed accordingly.

Key Applications

The interference model for a random two-hop relay link above can be used to analyze and manage interference in a wireless network. As shown in (5), the key issue is the distribution functions of the distance product in the relay link, considering the random location of the RS. The stochastic geometry approach can be employed to derive $F_{D_{s,h}D_{h,i}}(d)$ and $f_{D_{s,h}D_{h,i}}(d)$ in a random two-hop relay link (Song et al. 2013; Baccelli and Giovanidis 2015; Zhuang et al. 2010). For example, the following scenarios can be studied:

- For a cellular network, the BS communicates with a target user equipment (UE) via a two-hop relay link in a hexagonal cell. The BS is located at the center, and the RS is uniformly located inside the rhombus area covered by a directional antenna of the BS. The IS may be in the same or an adjacent cell, and it is interfered by the signal transmitted by the RS.
- For an ad hoc network, two stations communicate via a two-hop link without the constraint of their locations. The RS is uniformly located in a lens-like area determined by the SS and the DS.

Song et al. (2013) obtained the closed-form and approximation expressions of the distribution functions of the distance product, and similar approach can be extended to the other scenarios.

By plugging $F_{D_{s,r}D_{r,i}}(d)$ and $f_{D_{s,r}D_{r,i}}(d)$ into (4) and (5), the distribution functions of the interference power can be obtained. Then the network performance and interference management algorithms can be evaluated analytically with more insights on their properties.

Massive MIMO; Millimeter-wave communications; Per-beam synchronization

Definitions

Per-beam synchronization refers to a synchronization approach in wireless transmission where signal synchronization in time and frequency between the transmitter and the receiver is performed over each beam individually.

Background

Millimeter-wave massive multiple-input multiple-output (MIMO) is promising for future wireless communications (Swindlehurst et al. 2014; Cui et al. 2018; Huang et al. To appear; Liu

et al. 2018; Xiao et al. 2017). One challenge in realizing cellular wireless over millimeter-wave channels is to deal with the mobility issue (Roh et al. 2014; Andrews et al 2017). For the same mobile speed, the Doppler spread of millimeter-wave channels is orders-of-magnitude larger than that of classical wireless channels, while the delay spread does not change significantly over different frequencies, which may lead to system implementation bottleneck. Consider wideband millimeter-wave transmission employing orthogonal frequency division multiplexing (OFDM) modulation, for example. With perfect time and frequency synchronization in the space domain, the length of the cyclic prefix (CP) is usually set to be slightly larger than the delay span to mitigate channel dispersion in time, while the length of the OFDM symbol is usually set to be inversely proportional to the Doppler spread to mitigate channel dispersion in frequency (Hwang et al. 2009; Dahlman et al. 2014). As a result, the overhead of the CP will be much larger to deal with the same delay spread, and it might be difficult to design proper OFDM parameters.

There exist some works related to the above issue. For example, beam-based Doppler frequency compensation has been suggested in Chizhik (2004) and Va et al. (2017) for narrowband MIMO channels. In addition, reduced delay spread with narrow directional beams has been observed in recent millimeter-wave channel measurement results (Rappaport et al. 2015).

Massive MIMO Beam Domain Channel Model

Consider a single-cell massive MIMO system, where the base station equipped with an M -element uniform linear array (ULA) serves several users, each with a K -element ULA. Due to the small wavelength in millimeter-wave bands, the case where both the numbers of antennas at the base station and the users are sufficiently large is of practical interest (Andrews et al 2017), which is different from the massive

MIMO communications over lower frequency bands (Marzetta 2010).

Denote the complex baseband downlink of space domain channel frequency response matrix of user u as $\mathbf{G}_u$. Then the corresponding beam domain channel matrix can be represented as $\bar{\mathbf{G}}_u = \mathbf{F}_K^H \mathbf{G}_u \mathbf{F}_M^*$ where $\mathbf{F}_K$ is the $K \times K$ unitary discrete Fourier transform (DFT) matrix. Both transformation matrices, $\mathbf{F}_K$ and $\mathbf{F}_M$, can be interpreted as DFT beamforming operations performed at the base station and the users, respectively. Thus, $\bar{\mathbf{G}}_u$ is referred to as the beam domain channel frequency response matrix.

In the asymptotically large array regime, the fading of each of the beam domain channel elements tends to disappear when both the numbers of antennas at the base station and the users tend to infinity. The physical interpretation is intuitive. Specifically, beamforming can effectively divide the channels in the angle domain, and the partition resolution can be sufficiently high with sufficiently large numbers of antennas at both the base station and the users. Asymptotically, each propagation path can be resolved, and the beam domain channel element corresponds to the gain of a specific propagation path along a fixed AoA-AoD pair. Thus, the beam domain channel envelopes tend to remain a constant in both the time and the frequency domains (You et al. 2017).

Per-Beam Synchronization in Time and Frequency

Consider the OFDM-based millimeter-wave massive MIMO wireless transmission. The performance of OFDM-based transmission is sensitive to time and frequency offsets, so it is necessary to perform time and frequency synchronization to compensate for time and frequency offsets of the received signals. In particular, the received signals should be carefully adjusted so that the resultant minimum time offset and center frequency offset are aligned to zero (Hwang et al. 2009). The most common synchronization approach for MIMO systems is to compensate for the time and frequency offsets of the received signals in the space domain using the same time

and frequency adjustment parameters. Then the resultant channel frequency spread scales linearly with the carrier frequency for a given mobile velocity. Therefore, in order to support the same user mobility, the length of the OFDM symbol in millimeter-wave systems would be substantially reduced compared with that in the conventional microwave systems. Meanwhile, the length of the CP would be the same as that in the conventional microwave systems to deal with the same delay spread, which might lead to difficulty in selecting proper OFDM parameters.

Motivated by the beam domain massive MIMO channel properties in the time and frequency domains, per-beam synchronization in time and frequency, where adjustment of time and frequency offsets is applied to the signal over each receive beam individually, can be adopted to address the above issue (You et al. 2017). Compared with the conventional synchronization approach, the effective channel delay and frequency spreads can be reduced with the per-beam synchronization approach. In particular, the effective channel frequency spread is approximately reduced by a factor of the number of user antennas in the large array regime. In addition, the effective channel delay spread can also be reduced with per-beam synchronization, but the quantitative performance is difficult to establish. For the case in which a ring of scatterers is located around the users (Shiu et al. 2000; Pätzold and Hogstad 2006), the effective channel delay spread with per-beam synchronization is also reduced by a factor of the number of user antennas.

Per-beam synchronization can be exploited to simplify the implementation and improve the performance of millimeter-wave massive MIMO-OFDM systems. In particular, the number of user antennas also scales linearly with the carrier frequency for the same antenna array aperture although the maximum channel Doppler shift scales linearly with the carrier frequency. Thus, assuming a fixed antenna array aperture, the effective channel Doppler frequency spread over millimeter-wave bands becomes approximately the same as that over regular bands with per-beam synchronization, which can mitigate severe

Doppler effects over millimeter-wave channels. Moreover, the effective channel delay spread can be significantly reduced with per-beam synchronization, which can further lead to a substantial reduction in the CP overhead.

Key Applications

Per-beam synchronization can be adopted to deal with the mobility issue in millimeter-wave massive MIMO. The motivation of per-beam synchronization stems from the beam domain massive MIMO channel property that the fading of each of the beam domain channel elements tends to disappear in the asymptotic large array regime. For per-beam synchronization, signal synchronization in time and frequency between the transmitter and the receiver is performed over each beam individually. With per-beam synchronization, both the effective channel delay and Doppler frequency spreads can be approximately reduced by a factor of the number of antennas at the receiver in the large array regime with per-beam synchronization compared with the conventional synchronization approaches, which effectively mitigates the severe Doppler effect in millimeter-wave systems and leads to a significantly reduced CP overhead. Per-beam synchronization can be applied in massive MIMO transmission approaches such as the beam division multiple access transmission (Sun et al. 2015).

Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization

Configuration and management; Network function virtualization; Packet forwarding function; Performance prediction; Software router

Definitions

Performance modeling of a virtual network function (VNF) refers to a mathematical framework for characterizing the performance of a VNF under the configuration and allocated resources of the hosting commodity hardware.

Historical Background

Wireless network virtualization (WNV) has emerged as a key technology toward a road to the fifth-generation mobile communication (5G) networks. It enables the sharing of radio spectrum and infrastructure resources among multiple 5G services as well as multiple service providers. The adoption of virtualization is for facilitating the flexible and scalable deployment of 5G appliances as virtual network functions (VNFs) running on commodity hardware. Although this operational technique of WNV seems to be reasonable and cost-effective, it requires rethinking since the immaturity of VNF deployment is still a major concern (Mijumbi et al. 2016). This concern translates into the pressing need for the ability to quantify the performance of VNFs running on commodity hardware equivalent to that obtained from network functions (NFs) running on specialized hardware. In other words, sufficient allocated

resources and the optimal configuration of commodity hardware should be specified in order for a VNF to perform at its quality of service (QoS) requirement.

A common VNF for 5G virtual appliances running in the core network is a *packet forwarding function*. The critical challenge disrupting the rapid deployment of a *virtual packet forwarding function* (vPFF) is that different configurations of the hosting server yield different performances in terms of throughput and packet latency, making it impossible to guarantee the QoS. The throughput and packet latency of a vPFF regarding the allocated resources by a precise performance modeling has been seen as a key to quantify the sufficient amount of resources that should be assigned to the vPFF. Moreover, the performance modeling is also beneficial to properly configure a server for serving a vPFF such that its QoS can be guaranteed.

Performance modeling for a packet forwarding function of a hardware router has been extensively studied for decades, e.g., Kim and Kim (2003) and Kiasari et al. (2013). Due to lacks of considering the effect of processor sharing and the interaction of CPU processing with an interrupt handling scheme in a server, these existing analytical models may not be applied for modeling the performance of a vPFF. Alternatively, simulation (Meyer et al. 2014; Beifub et al. 2015) and machine learning (ML) (Riccobene et al. 2016) approaches have been gained more attention as tools for estimating the performance of a vPFF. However, these approaches require a large number of samples of measured data for calibration.

Apart from the aforementioned techniques, a mathematical approach for modeling the performance of a vPFF with a two-dimensional Markov chain has been studied in Gallardo et al. (2016). The model was built upon the assumption that the time the packets wait in Rx queues depends on the implemented polling strategies. However, this model requires the mean packet processing time, mean server vacation time, and queue length as input in order to derive the average packet latency. This approach may not be possible for the realistic WNV systems since the mean packet

processing time and mean server vacation time could not be measured. Hence, this article will present a simple and precise performance modeling of vPFF and introduce an integration of the performance modeling into NFV management and orchestration (NFV-MANO).

Performance Modeling of a Virtual Packet Forwarding Function

Maximum Throughput

The studies in Gallenmüller et al. (2015) and Suk-somboon et al. (2018) reveal that the maximum throughput of a vPFF depends on the allocated resources and configuration of a host server, i.e., Ethernet bandwidth, CPU speed, the number of receiving (Rx) queues, and the number of concurrently running CPUs.

Figure 1 illustrates that the maximum throughput of vPFF is bounded by Ethernet bandwidth and CPU speed. While larger Ethernet bandwidth and higher CPU speeds yield higher maximum throughput, more Rx queues cause the lower maximum throughput. Regarding the observations in Suksoomboon et al. (2018), the average CPU consumption in cycles per packet is linearly scaled by the number of Rx queues, denoted by q . Denote m the maximum number of

Rx queues. Thus, the average CPU consumption per packet can be formulated as a linear function of the number of Rx queues q and q' , where $q \neq q'$ and $q, q' = 1, 2, \dots, m$, as following,

$$C(q) = C(q') + (q - q')\alpha, \quad (1)$$

where $C(q)$ and $C(q')$ are the average CPU consumption per packet with q and q' Rx queues, respectively, and α is the extra CPU consumption due to an added Rx queue. Note that the formula in (1) is flexible enough, thereby observing any two different Rx queue configurations. Hence, the maximum throughput can be computed by minimizing between the maximum throughput bounded by Ethernet bandwidth (i.e., $r_{\max} \leq \frac{v_{\text{eth}}}{b}$ for packet size b and v_{eth} Ethernet bandwidth) and the maximum throughput given q Rx queues bounded by CPU speed F_{cpu} (i.e., $c_{\max}(q) \leq \frac{F_{\text{cpu}}}{C(q)}$).

Besides, allocating more the number of CPU cores to vPFF can increase the maximum throughput of a vPFF. However, their relationship is nonlinear due to the cache contention. Figure 2 demonstrates the CPU architecture for analysis. Define a *solo run* as a single CPU core that processes a packet forwarding function without sharing the last-level cache (LLC) and *corunners* as the other CPU cores that concurrently run the

Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization, Fig. 1 Relationship between CPU consumptions per packet and maximum throughput. (Region 1 represents the area where the maximum throughput is bounded by Ethernet

bandwidth, and Region 2 represents the area where the maximum throughput is bounded by CPU speeds F_{cpu} .) Higher CPU speed (e.g., $F_{\text{cpu}} < F''_{\text{cpu}} < F'_{\text{cpu}}$) enlarges Region 2

Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization, Fig. 2 An example of CPU architecture with four CPU cores in a single socket

same function with another CPU core, where two or more CPU cores are assigned to a vPFF and these CPU cores share the same LLC. Regarding the observations in Suksomboon et al. (2017), the CPU consumption per packet is *dilated* from that of a single CPU core due to the cache contention by the corunners, which share the same LLC. The linear increase of the number of cache misses at LLC corresponds to the increasing number of CPU cores assigned to a vPFF. Thus, the *dilated CPU consumption (DCC)* is affected by cache contention in which cache hits turn to misses.

Let $\bar{\alpha}$ be the extra CPU consumption spent for processing a packet once all cache hits of a solo run become cache misses by corunners. Let h be the number of cache hits per second at the LLC with a solo run. Let λ_{solo} be the maximum throughput of a solo run. Therefore, $\frac{h}{\lambda_{\text{solo}}}$ refers to the number of cache hit references per packet at the LLC of a solo run. Hence, the number of cache hit references per packet with corunners becomes $\frac{nh}{\lambda_{\text{solo}}}$, where n is the number of CPU cores. Define ξ as the time difference between accessing the LLC and the system memory. Thus, ξ can be transformed to the number of CPU cycles by ξF_{cpu} cycles. Hence, $\bar{\alpha}$ can be estimated by

$$\bar{\alpha} = \frac{\xi F_{\text{cpu}} n h}{\lambda_{\text{solo}}}. \quad (2)$$

To generalize (2), let $F_{\text{cpu},i}$ be the CPU speed of core i . Hence, $\bar{\alpha} = \frac{\xi h \sum_{j=1}^n F_{\text{cpu},i}}{\lambda_{\text{solo}}}$, and $\bar{\alpha}$ in (2) can be seen as its special form, when all cores have the same CPU speed.

The DCC is estimated upon the assumption that not all but some packets will suffer the cache contention. This assumption is based on the fact that only cache hits turning to cache misses cause CPU spends more cycles to retrieve data from the memory. Meanwhile, the probability of cache misses turning to hits is very small, so this value can be omitted. Therefore, the probability of cache misses being still misses is close to one. Let p be the probability of cache references that were hits at a solo run being still hits with corunners, called *cache-hit-to-hit*—and $p' = 1 - p$ be the probability of cache references that were hits at a solo run becoming misses with corunners—called *cache-hit-to-miss*. Consequently, the packets are divided into two groups: (1) the packets that did not suffer the cache contention and (2) the packets that suffered the cache contention. CPUs spend C cycles for processing packets of the first group and $C + \bar{\alpha}$ for the second group. Let p_i be the probability that CPU core i will not suffer the cache contention by corunning with the other CPU cores j , where $j \neq i$ and $j = 1, \dots, n$, which share the LLC with CPU core i , and $1 - p_i$ is vice versa. This p_i can be referred to as the probability of cache-hit-to-hit,

and $1 - p_i$ can be referred to as the probability of cache-hit-to-miss. Let u_i be the CPU utilization of CPU core i , where $0 \leq u_i \leq 1$ for $i = 1, \dots, n$. The probability of cache-hit-to-hit is obtained by $p = p_i = \min \left\{ \frac{1}{\sum_{j=1}^n u_j}, 1 \right\} \approx \frac{1}{n}$, where $u_j \approx 1$ since a server is overloaded. The maximum throughput for multicore processing systems can be estimated by

$$c_{\max} \approx n F_{\text{cpu}} \left(\frac{C + p\bar{\alpha}}{C(C + \bar{\alpha})} \right). \quad (3)$$

where $F_{\text{cpu},i} = F_{\text{cpu}}$. Note that $\sum_{i=1}^n u_i \geq 1$, where $n > 1$.

Packet Latency

Regarding the observations in Suksomboon et al. (2018), the shapes of the packet latency distributions of vPFF are likely asymmetric bell-shaped distributions, thereby fitting the Erlang- k distributions. The probability density function (PDF) is given by

$$f(x; (k, \beta, \gamma)) = \frac{\beta^k (x - \gamma)^{k-1} e^{-\beta(x-\gamma)}}{(k-1)!}, \quad (4)$$

where the shape parameter $k \in \mathbb{I}^+$ is a positive integer, the scale parameter $\beta \in \mathbb{R}^+$ is a positive real number, and the location parameter $\gamma \in \mathbb{R}^+$ is a positive real number (i.e., $\gamma = \arg \min_x \{x : f(x; (k, \beta, \gamma)) > 0\}$). Fitting an Erlang- k distribution to a packet latency distribution is to select k , β , and γ for minimizing the least-squares error between the measurement result and the fitting curve. The average packet latency can be calculated by the mean of the Erlang- k distribution equal to $\frac{k}{\beta} + \gamma$, and its variance is equal to $\frac{k}{\beta^2}$. Note that the curve fitting method is not for modeling the average packet latency, but it is used for studying the relationship of the Erlang- k parameters to the configured and the observed parameters.

Let $\tau(s)$ be the average packet latency corresponding to a vector of configuration parameters denoted by s , where $s := (q, R, B, F_{\text{cpu}})$ is a four-tuple of q Rx queues, ring size buffer R , netdev_budget B , and CPU speed F_{cpu} . The

average packet latency can be obtained by estimating $k(s)$, $\beta(s)$, and $\gamma(s)$ as functions of s and substituting them into $f(x; (k(s), \beta(s), \gamma(s)))$ as

$$\tau(s) = E[f(x; (k(s), \beta(s), \gamma(s)))] = \frac{k(s)}{\beta(s)} + \gamma(s). \quad (5)$$

To estimate the Erlang- k parameters, it is required to find the relationship between the Erlang- k parameters to the configured parameters and the measurable parameters of a server's behavior. The observations in Suksomboon et al. (2018) demonstrates the relationship between the Erlang- k parameters to the configured parameters. Nevertheless, this relationship is not sufficient for estimating the Erlang- k parameters. To this end, it requires the understanding of the relationship between the Erlang- k parameters and the measurable parameters of a server's behavior as shown in Fig. 3.

According to the physical meanings of Erlang- k distribution, the packet latency can be represented as a random variable X that has an Erlang- k distribution for $k = 1, 2, \dots$ with mean k/β , if X is the sum of k independent random variables $X_1, X_2, \dots, X_k$ having a common exponential distribution with mean $1/\beta$. Particularly, it can be expressed as series of k exponential phases. Regarding this assumption, the packet latency contains k identical phases connected in series, each with exponentially distributed time. The mean duration of each phase is $\bar{X}/k$, where $\bar{X}$ denotes the mean of the whole time span. To divide the whole process of packet forwarding into k phases, the assumption is made that the series of packets that are moved from the `poll_list` to be processed one-by-one and to wait at Qdisc before they depart from the system have the relationship with the series of k phases. The assumption is reasonable because the time that a packet waits for processing plus processing time dominates the other waiting time. The study in Suksomboon et al. (2018) demonstrates that $k(s)$ depends on q given R, B, F_{cpu} are fixed. Then, it can be shorten as $k(q)$ and given by

$$k(q) = \lceil k(1)/q \rceil, \quad q = 2, 3, \dots, m \quad (6)$$

Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization, Fig. 3
Linux network stack-based packet forwarding for a single core server

where $k(1)$ is obtained by the curve fitting of the measurement result of configuring $q = 1$. Note that the formula in (6) is required in only one configuration.

Next, $1/\beta$ refers to the mean of an exponential distribution of variable X_i for all $i = 1, 2, \dots, k$. The factor that makes the mean of the variable in each phase scale due to changing q and R is the amount of time that the packets have to wait in the Rx DMA ring buffers. Thus, it can be assumed that β or $\beta(q)$ has a relationship with the total Rx hardware IRQ (Rx h-IRQ) rate, which is affected by these two parameters q and R . The received packets are uniformly distributed to all q ring buffers when the equally weighted flow director is applied. Thus, the packet arrival rate at each queue is equivalent to λ_{out}/q for weighted flow director $1/q$ since the packets were dropped before entering the queues. Define $\sigma(q, \lambda_{\text{in}})$ as the total Rx h-IRQ rate of all q Rx queues given λ_{in} and then the Rx h-IRQ rate of each Rx queue can be expressed as $\sigma(q, \lambda_{\text{in}})/q$. The Rx h-IRQ rate depends on the packet arrival rate at an Rx queue. For convenience, the Rx h-IRQ rate of each Rx queue is defined as $\psi(\lambda') = \sigma(q, \lambda_{\text{in}})/q$, where packet arrival rate at a Rx queue $\lambda' = \lambda_{\text{in}}/q$. Since the received packets are uniformly distributed to all q ring buffers and the Rx h-IRQ

rate of each queue depends on the packet arrival rate at each queue, $\psi(\lambda') = \sigma(q, \lambda_{\text{in}})/q$, where $\lambda_{\text{in}} = \lambda_{\text{out}}(q)/q$ and $\lambda_{\text{out}}(q)$ is the maximum throughput given q . Thus, with q Rx queues, the mean time of packets being waiting in their Rx DMA ring buffers can be rewritten as

$$\frac{1}{\beta(q)} = q \left(\frac{\psi(\lambda_{\text{out}}(q)/q)}{\lambda_{\text{out}}(q)/q} \right) = \frac{q^2 \psi(\lambda_{\text{out}}(q)/q)}{\lambda_{\text{out}}(q)}. \quad (7)$$

Since $\gamma(q)$ implies the minimum time that a packet spending in a server, it can be intuitively estimated for each exponential phase by sampling an instance from the time of waiting for a Rx h-IRQ $\frac{q}{\psi(\lambda_{\text{out}}(q)/q)}$, and the time of the first packet arrives $\frac{1}{\lambda_{\text{out}}(q)/q}$. By assuming that these two terms are the independent random variables, their convolution is equal to their multiplication. This time spans according to the variance of the distribution, i.e., $k(q)/(\beta(q))^2$. That is $\gamma(q)$ is given by

$$\gamma(q) = \left(\frac{q^2 k(q)}{(\beta(q))^2 \psi(\lambda_{\text{out}}(q)/q) \lambda_{\text{out}}(q)} \right). \quad (8)$$

Key Applications

The abstraction of underneath resources with virtualization or network slicing opens new room

Performance Modeling of Virtual Packet Forwarding Functions for Wireless Network Virtualization, Fig. 4
Integration of performance modeling and NFV-MANO architecture

for mobile network businesses in which various sliced 5G services and virtual 5G appliances can be separately operated on top of these shared resources. This creation is expected to expand the telecommunications market to mobile virtual network operators (MVNOs) and let them enjoy a new playground of this sharing. It also helps in reducing the capital expenditure (CapEX) and operational expenditure (OpEX) of radio access network (RAN) and core network of mobile network operators (MNOs).

To allocate the virtual resources to each service slice optimally, the precise performance modeling of vPFF is a useful tool for assisting the NFV-MANO. Figure 4 presents the modules for the performance modeling of vPFF incorporated in NFV-MANO.

Definitions

Pilot reuse refers to a pilot approach in wireless transmission where pilot signals adopted in the same cell can be non-orthogonal. Massive multiple-input multiple-output (MIMO) transmission employs a large number of antennas at the base station (BS) to serve a relatively smaller number of user terminals (UTs) simultaneously. For conventional orthogonal pilot approach, the pilot overhead scales linearly with the number of antennas, which constitutes the system bottleneck. Pilot reuse can be adopted to mitigate the pilot overhead issue in massive MIMO.

Background

Massive MIMO is a promising technology for future wireless systems due to its potential large gains in spectral efficiency and energy efficiency (Marzetta 2010; Wang et al. 2014). Channel state information (CSI) at the BS is of importance in massive MIMO transmission. In realistic systems CSI is typically obtained with the assistance of the periodically inserted pilot signals (Tong et al. 2004). For conventional orthogonal pilot approach, the pilot overhead is proportional to the number of antennas, which might become the system bottleneck for throughput in massive MIMO.

Massive MIMO channel properties can be adopted to address the above issue. Wireless channels are sparse in many typical propagation scenarios; most channel power is concentrated in a finite region of delays and/or angles due to limited scattering (Tse and Viswanath 2005; Liu et al. 2018; Xiao et al. 2017; Yang and Xiao 2018). Such channel sparsity can be resolved in the angle domain in massive MIMO due to the relatively large antenna array apertures (Payami and Tufvesson 2012; Gao et al. 2013). In addition, channel sparsity patterns, i.e., channel power distributions in the angle-delay domain, for different UTs are usually different. When pilots adopted by different UTs are properly scheduled according to the above channel properties, channel acquisition can be achieved simultaneously in an almost interference-free manner as with conventional orthogonal pilot approach (You et al. 2015, 2016; Zhong et al. 2015).

Massive MIMO Channel Model

Consider a single-cell wideband massive MIMO system, where the base station equipped with an M -element uniform linear array serves K single-antenna UTs. Orthogonal frequency division multiplexing (OFDM) modulation is adopted with the number of subcarriers being N_c and the sample length of the guard interval being N_g . Denote the uplink channel gain between the antenna of the k th UT and the antennas of the BS over OFDM symbol ℓ and subcarrier n as $\mathbf{g}_{k,\ell,n}$. Then the k th UT's channel at OFDM symbol ℓ over all subcarriers can be represented as $\mathbf{G}_{k,\ell} = [\mathbf{g}_{k,\ell,0} \ \mathbf{g}_{k,\ell,1} \ \dots \ \mathbf{g}_{k,\ell,N_c-1}]$. Motivated by the physical channel modeling approach (You et al. 2015, 2016), the angle-delay domain channel response matrix (ADCRM) of UT k at OFDM symbol ℓ can be defined as $\mathbf{H}_{k,\ell} = \mathbf{F}_M^H \mathbf{G}_{k,\ell} \mathbf{F}_{N_c \times N_g}^*$ where $\mathbf{F}_M$ denotes the $M \times M$ unitary discrete Fourier transform (DFT) matrix and $\mathbf{F}_{N_c \times N_g}$ denotes the matrix composed of the first N_g columns of the DFT matrix $\mathbf{F}_{N_c}$.

For OFDM-based massive MIMO channels, different elements of the ADCRM $\mathbf{H}_{k,\ell}$ are approximately mutually statistically uncorrelated (You et al. 2015, 2016), which lends the ADCRM its physical interpretation. Specifically, different elements of the ADCRM correspond to the channel gains for different incidence angles and delays, which can be resolved in massive MIMO-OFDM with a sufficiently large antenna array aperture. In addition, the statistics of the elements of ADCRM corresponds to the average channel power in the angle-delay domain and can be employed for pilot design in OFDM-based massive MIMO transmission.

Channel Acquisition with Pilot Reuse

Direct minimum mean square error (MMSE) estimation of the space-frequency domain channel response matrix $\mathbf{G}_{k,\ell}$ in massive MIMO is difficult to implement in practice due to the high complexity in large dimensional matrix inversion operation. However, channel estimation can be greatly simplified via properly exploiting the massive MIMO-OFDM channel properties. The BS can first estimate the ADCRM; then the space-frequency domain channel response matrix estimates can be readily obtained via exploiting the unitary equivalence between the angle-delay domain channels and the space-frequency domain channels while maintaining the same channel acquisition performance in terms of MSE.

Adjustable phase shift pilot (APSP) is one kind of pilot reuse approach for massive MIMO-OFDM channel acquisition (You et al. 2016). For the APSP approach, one sequence along with different adjustable phase-shifted versions of itself in the frequency domain is adopted as pilots for different UTs. APSPs are different from conventional phase shift orthogonal pilots (PSOPs) (Li 2002; Barhumi et al. 2003; Chi et al. 2011), in which phase shifts for different pilots are fixed and phase shift differences between different pilots are no less than the maximum channel delay (divided by the system sampling duration) of all the UTs. Since in the APSP

approach, the phase shifts for different pilots are adjustable, more pilots are available compared with conventional PSOPs, which leads to significantly reduced pilot overhead.

With APSPs, the sum MSE can be minimized when phase shifts for different pilots are properly scheduled. With frequency domain phase-shifted pilots, equivalent channels will exhibit corresponding cyclic shifts in the delay domain. If the equivalent channel power distributions in the angle-delay domain for different UTs can be made non-overlapping after pilot phase shift scheduling, the pilot interference effect can be eliminated, and the sum MSE of channel estimation can be minimized. However, such an optimal condition cannot always be met in practice, but pilot phase shift scheduling can still be beneficial. Pilot scheduling can be performed based on, e.g., MMSE criterion. The scheduling problem is combinatorial, and the optimal solution must be found through an exhaustive search. Motivated by the optimal condition for channel acquisition, simplified pilot phase shift scheduling algorithms can also be developed (You et al. 2015, 2016).

Key Applications

Pilot reuse can be adopted to mitigate the pilot overhead issue in massive MIMO. The idea of pilot reuse is motivated from the fact that, in realistic outdoor wireless propagation environments where the BS is located at a high altitude, the scattering around the BS is usually limited and the MIMO channels are not spatially isotropic. For UTs with channels lying in almost orthogonal spatial directions, pilot reuse is feasible and beneficial. For wideband massive MIMO-OFDM channels, APSP is one kind of pilot reuse approach that can efficiently reduce the pilot overhead and further improve the wireless transmission performance.

Pilot Spoofing Attack

Technology, Wuhan, China

Synonyms

Pilot contamination attack; Spoofing attack

Definitions

Pilot spoofing attack refers to an active attack in wireless networks, where active eavesdroppers (Eves) manipulate the channel estimation to increase the eavesdropping rate. In time division duplex (TDD) systems with channel reciprocity, the downlink channel state information (CSI) can be acquired through uplink channel training. A smart active Eve may hack such channel estimation process by sending an identical pilot sequence to the base station (BS), causing an erroneous channel estimation at the BS and more information leak to the Eve.

Background

By exploiting the randomness of wireless medium, physical layer security can provide lightweight security solution for low-cost Internet of Things (IoT) devices and has been regarded as a promising solution to enhance security in emerging large-scale heterogeneous networks (HetNets) (Mukherjee 2015; Poor and Schaefer 2017). The information-theoretical security was investigated by Wyner considering a wiretap

channel model in Wyner (1975), where Alice wants to transmit a confidential message W to Bob over a noisy channel while keep it secret to Eve, as shown in Fig. 1. Specifically, Alice encodes the message into a code word X^n with length n to enable Bob successfully decode W based on his observation Y^n . Wyner measured secrecy by equivocation or conditional entropy, and it is required that $\frac{1}{n}H(W|Z^n) = \frac{1}{n}H(W)$ to guarantee that W is kept secret from Eve. This criterion can also be equivalently written as $\lim_{n \rightarrow \infty} \frac{1}{n}I(W; Z^n) = 0$. Wyner characterized the secrecy capacity for the degraded wiretap channel and showed that secrecy capacity can be achieved through stochastic encoding. Since then, plenty of researches have been conducted. For the degraded wiretap channel with additive Gaussian noise, the secrecy capacity is determined by the capacity difference between the main channel and the wiretap channel Leung-Yan-Cheong and Hellman (1978). Hence, positive secrecy capacity is achievable only if the eavesdropping channel is a degraded version of the main channel. From the perspective of the Eve, to degrade the secrecy performance, advantages in the eavesdropping channel over the main channel can be realized by contaminating the channel estimation in the reverse channel training phase in TDD systems Zhou et al. (2012). Specifically, the Eve may send an identical pilot signal like a legitimate user in the uplink channel state information (CSI) acquisition phase and thus can flexibly control the eavesdropping rate by changing the uplink transmission power used for pilot spoofing attack. When the uplink transmission power of the Eve is large enough, channel estimation at the legitimate transmitter side will be dominated by the eavesdropping channel, and the probability of achieving positive secrecy rate will approach to zero.

Inspired by the pilot contamination phenomenon in multicell systems, pilot spoofing attack was firstly investigated in Zhou et al. (2012). It was shown that the effective signal-to-noise ratio (SNR) of the Eve may be higher than that of the legitimate receiver with proper power allocation for a full-duplex active Eve. To detect the pilot spoofing attack, an energy ratio

Pilot Spoofing Attack, Fig. 1 The Wyner wiretap channel model

detector was proposed in Xiong et al. (2015) by comparing the received signal power at the transmitter and receiver. By superimposing a random sequence onto the training sequence at the legitimate receiver and using the minimum description length (MDL) criterion, pilot contamination attack can be detected effectively (Tugnait 2015). More recently, a new random channel training (RCT) scheme was proposed in Wang et al. (2018a) to combat both the pilot spoofing and jamming attack. Through allocating multiple pilot sequences to a legitimate user and random pilot sequence selection, both the legitimate channel and eavesdropping channel can be estimated by exploiting the spatial channel statistics. However, this kind of scheme requires more training sequences and thus may not be applicable to multiple users case.

Due to the inherent similarity between pilot spoofing attack and pilot contamination in massive MIMO, the impact of pilot spoofing attack in massive MIMO has also been investigated. It was shown that the ergodic secrecy rate suffered a ceiling effect due to the pilot contamination in Zhu et al. (2014). In Basciftci et al. (2015), the authors revealed that the maximum secure degree of freedom (DoF) approaches to zero in the presence of active pilot spoofing attack. In Wu et al. (2016), by incorporating pilot contamination and pilot attack from multi-antenna active Eves in a TDD multicell multi-user massive MIMO system, a closed-form expression of the asymptotic achievable secrecy rate was derived with matched filter precoding and artificial noise. It was proved that the impact of the active Eve can be completely eliminated when the transmitting correlation matrices of the users and the

Eve are orthogonal, and robust design against pilot contamination attack was also developed. Furthermore, it was shown that deploying more base stations is more effective to improve the secrecy performance for a massive MIMO system under pilot contamination and pilot spoofing attack Wang et al. (2018b).

Impact of Pilot Spoofing Attack

To clarify the impact of pilot spoofing attack, we consider a single-cell multi-user massive MIMO system, where the BS is equipped with N antennas, whereas users and Eves are equipped with a single antenna each. We assume that each user is eavesdropped by an Eve. The channel from the k th user to the BS is denoted by $\sqrt{\beta_{u_k}}\mathbf{h}_k$, where β_{u_k} is the large-scale path loss and $\mathbf{h}_k$ is the small-scale Rayleigh fading. Similarly, the channel from the k th Eve is $\sqrt{\beta_{e_k}}\mathbf{g}_k$, with β_{e_k} being the large-scale path loss and $\mathbf{g}_k$ the small-scale fading vector.

We assume that the BS assigns orthogonal pilots for the K users within its cell, and Eve knows the training sequence assigned to the targeted user. Then the received signal at the BS in the uplink training stage can be expressed as

$$\mathbf{Y}_p = \sum_{k=1}^K \left(\sqrt{P_{u_k}\beta_{u_k}}\mathbf{h}_k\mathbf{s}_k^H + \sqrt{P_{e_k}\beta_{e_k}}\mathbf{g}_k\mathbf{s}_k^H \right) + \mathbf{N}, \quad (1)$$

where $\mathbf{s}_k$ is the pilot sequence assigned to the k th user with length τ_p and satisfies $\mathbf{s}_k^H\mathbf{s}_l = \delta_{kl}\tau_p$ with $\delta_{kl} = 1$ when $k = l$ and $\delta_{kl} = 0$ otherwise.

Note that P_{u_k} and P_{e_k} denote the uplink transmission power of the user and Eve, respectively, and $\mathbf{N}$ is the white Gaussian noise received at the BS. After correlating the received signal with the corresponding pilot sequence, the observed channel of the k th user can be expressed as

$$\mathbf{y}_k = \frac{\mathbf{Y}_p \mathbf{s}_k}{\tau_p} = \sqrt{P_{u_k} \beta_{u_k}} \mathbf{h}_k + \sqrt{P_{e_k} \beta_{e_k}} \mathbf{g}_k + \mathbf{n}_k. \quad (2)$$

Given the large-scale path loss, an MMSE channel estimation is given by Bai and Heath (2016) and Björnson et al. (2016)

$$\begin{aligned} \hat{\mathbf{h}}_k &= \frac{\sqrt{P_{u_k} \beta_{u_k}}}{\Sigma_k} \mathbf{y}_k = \frac{P_{u_k} \beta_{u_k}}{\Sigma_k} \mathbf{h}_k \\ &+ \frac{\sqrt{P_{u_k} P_{e_k} \beta_{u_k} \beta_{e_k}}}{\Sigma_k} \mathbf{g}_k + \frac{\sqrt{P_{u_k} \beta_{u_k}}}{\Sigma_k \Sigma_k} \mathbf{n}_k, \end{aligned} \quad (3)$$

where $\Sigma_k = P_{u_k} \beta_{u_k} + P_{e_k} \beta_{e_k} + \frac{\sigma^2}{\tau_p}$.

After uplink channel training, the BS uses the estimated channels to transmit downlink data to each user, and then the received signal at the k th user and k th Eve can be expressed as

$$\begin{aligned} y_k &= \sqrt{\phi_k P \beta_{u_k}} \mathbf{h}_k^T \mathbf{w}_k m_k \\ &+ \sum_{l \neq k}^K \sqrt{\phi_l P \beta_{u_k}} \mathbf{h}_k^T \mathbf{w}_l m_l + n_k, \end{aligned} \quad (4)$$

and

$$\begin{aligned} y_{e_k} &= \sqrt{\phi_k P \beta_{e_k}} \mathbf{g}_k^T \mathbf{w}_k m_k \\ &+ \sum_{l \neq k}^K \sqrt{\phi_l P \beta_{e_k}} \mathbf{g}_k^T \mathbf{w}_l m_l + n_{e_k}, \end{aligned} \quad (5)$$

respectively. Note that P is the total transmission power and ϕ_k , $\mathbf{w}_k$, and m_k are the power allocation, precoding vector, and intended message to the k th user, respectively. For a maximum-ratio transmission (MRT) scheme based on the estimated channel, i.e., $\mathbf{w}_k = \hat{\mathbf{h}}_k^* / \|\hat{\mathbf{h}}_k^*\|$, it can be seen that the desired signal for Eve satisfies $\lim_{N \rightarrow \infty} \frac{1}{N} |\mathbf{g}_k^T \mathbf{w}_k|^2 \rightarrow 0$ due to the correlation

between $\mathbf{g}_k$ and $\hat{\mathbf{h}}_k$. Therefore, the eavesdropping rate will not vanish by increasing the number of antennas in the presence of pilot spoofing attack.

Challenges and Open Problems

Considering the impact of pilot spoofing attack on the achievable secrecy performance, many challenges still need to be addressed:

- Pilot spoofing attack detection: Since the Eve uses the same pilot sequence with the legitimate user, the BS is usually unaware of the presence of pilot spoofing attack, which makes it more difficult to adopt countermeasure techniques. Therefore, effective detection schemes should be designed.
- Accurate legitimate channel estimation: To achieve secure transmission in the presence of pilot spoofing attack, advanced channel training schemes should be designed to obtain accurate channel estimations, especially in multiple Eves case. One possible approach is to exploit the uplink transmitted data and adopt the eigenvalue decomposition to estimate the channel eigenspace. Moreover, advanced double-training-based approaches may also be exploited to achieve accurate channel estimation.

Key Applications

Physical layer security is an appealing security solution for large-scale and resource-constrained networks, particularly in HetNet and machine-type communications, such as Internet of Things.

Definitions

In wireless networks, data transmission should not be bothered by other interferences in the environment including background noise and interferences from other signals. Power control for data transmission is a primary resource allocation technique in wireless networks to guarantee successful data transmission. The power control technique has two goals. The first one is to provide each data signal proper quality without causing unnecessary interference to other signals. The second one is to reduce the total energy consumption in order to prolong network lifetime.

Historical Background

The interferences among different wireless transmission signals are major factors that influence the quality of data transmission in wireless networks. Once a node in a wireless network wants to transmit data to another node, the transmission signal will also cause interferences to its neighbors. As illustrated in Fig. 1, the transmission signals of nodes *A* and *B* interfere the data reception of other nodes. Node *A* may interfere nodes *B*, *C*, and *D*, and node *B* may interfere nodes *A*, *C*, and *D*. Furthermore, a signal with a high strength will cause more interferences. The ratio between signal and interference is named as Signal-to-

Interference Ratio (SIR) (Stanczak et al. 2009). In order to improve data transmission quality and make sure that data can be successfully transmitted, the SIR of each signal should satisfy some certain constraints.

In early years, i.e., 1980s or 1970s, some power control schemes were proposed aiming at balancing the SIR of data transmission links Aein (1973), Nettleton and Alavi (1983) and improving wireless link quality. The method in Nettleton and Alavi (1983) is only based on simple algebra, but it can increase link capacity by 30–100% compared with a non power control wireless system. The authors in Zander (1992) defined a measurement named *Interference Probability* to measure the performance of the power control algorithms. Suppose wireless data transmission requires an SIR threshold γ , under which data cannot be transmitted successfully, then the *Interference Probability* is the probability that the SIR is less than γ . As proved in Zander (1992), there is an upper bound of the *Interference Probability* achieved by all the power control algorithms, and the above SIR-balancing power control algorithms are optimal.

The above power control schemes all assume that the transmission power can be continuously adjusted and the energy capacity of each node is infinite. However, as mentioned in Grandhi and Zander (1994), such an assumption is very optimistic since the transmission nodes in a wireless network are always hand-held devices with limited energy capacity. Thus, in 1990s and 2000s, many authors Grandhi and Zander (1994), Shah et al. (1998), Goodman and Mandayam (2000), Xiao et al. (2001) investigated how to improve the SIR of signals and optimize energy consumption as well. The work in Grandhi and Zander (1994) considers a maximum transmitted power P_{max} , and the SIR is minimized with the power of each signal being less than P_{max} . Other works, such as Shah et al. (1998), Goodman and Mandayam (2000), Xiao et al. (2001, 2003), Saraydar et al. (2002), consider network utility functions to improve data transmission quality and reduce energy consumption. Although the utility function proposed in each work is different, all the works use SIR as a major metric and energy

Power Control for Data Transmission in Wireless Networks, Fig. 1 Interferences between different nodes. The transmission signals of nodes *A* and *B* interfere the data reception of other nodes. Node *A* may interfere nodes *B*, *C*, and *D*, and node *B* may interfere nodes *A*, *C*, and *D*

consumption as a penalty. The power control process is formulated as a noncooperative game in these papers, and each node in a wireless network is treated as a player and tries to maximize its own utility. Thus, if the game researches a Nash equilibrium, then the global utility of the network is maximized.

The above methods all aim at improving signal quality. However, the authors in Yates (1995) and Li and Ephremides (2007) recommended that instead of optimizing signal capacity, prolonging node lifetime is more important. Thus, in Yates (1995) and Li and Ephremides (2007), some power control methods have been proposed to minimize the total energy consumption and guarantee a proper quality of each signal.

Although power control for wireless data transmission has been investigated in several decades, it is still an important research area in the recent years. The authors in Karipidis et al. (2015) proposed an SIR-balancing method with the assumption that the receivers in a network have an interference cancelation capability. It means the receivers can decode interfering signals whenever these interfering signals are strong enough. Zappone et al. (2016) and (2018) proposed some power control methods in 5G wireless networks.

Key Applications

Power control for wireless data transmission is involved in the areas related to wireless communications, such as communications among satellites, mobile cellular network users, and so on. In the future, it can also be used in 5G wireless networks, edge computing techniques, and so on.

Definitions

Power control in wireless networks, broadly speaking, is the intelligent control of transmitters' power output to achieve good system performance, such as network capacity, network connectivity, and lifetime of network devices and even the network.

Historical Background

Power control in wireless networks has been systematically studied since the 1970s. Over the last two decades, wireless networks (e.g., cellular networks and WiFi networks) have been exponentially growing and making transformative impacts on society. Due to the broadcast nature of wireless communication, wireless networks are susceptible to interference, particularly in interference-limited systems, such as CDMA systems. Power control helps to mitigate mutual interference among the users, so as to ensure efficient spectral reuse and desirable user experience. Besides interference management, power control can help to minimize the overall energy consumption, which is particularly important for the lifetime of mobile devices with limited battery power. Moreover, due to the uncertainty and time-varying nature of wireless channels, power control is important for maintaining the connectivity between the transmitter and the receiver by ensuring a minimum level of received signal. Extensive research on wireless network power control has produced a wide and deep set of

results in terms of modeling, analysis, and design (see Chiang et al. 2008; Gunnarsson 2004).

Foundations

Power control in wireless networks adopts a radio link model, in which each link consists of a dedicated transmitter-receiver pair and the transmitted power of each link appears as interference to other links (see Fig. 1). Let p_l be the transmit power of link l and h_{kl} be the channel gain between link k 's transmitter and link l 's receiver. The receiver of link l receives the signal at the power of $h_{ll}p_l$ and is subject to the total interference $\sum_{k \neq l} h_{kl}p_k$ and the noise n_l . The quality of the received signal of link l is quantified by the signal-to-interference-plus-noise ratio (SINR), i.e., $\gamma_l = h_{ll}p_l / (\sum_{k \neq l} h_{kl}p_k + n_l)$.

A power control problem often involves an optimization formulation with transmit power as optimization variables and aims to optimize system utility or resource cost subject to various constraints (e.g., total transmit power, maximum transmit power for each link). For example, an increasing convex function (e.g., linear function) of transmit power can be used as the objective function. For system utility, QoS-based utility function is often used and assumed to be additive across links, i.e., $U(\boldsymbol{\beta}) = \sum_l U_l(\beta_l)$, where $\boldsymbol{\beta}$ is a vector of metrics. One commonly used QoS

Power Control in Wireless Networks, Fig. 1 Radio link model, where “Tx” and “Rx” represents transmitter and receiver, respectively (Yang et al. 2012)

metric is throughput, which is a function of SINR and in turn a function of transmit powers. The throughput is often assumed to be the Shannon rate achievable over Gaussian flat, fading channels, i.e., $\beta_l = w \log(1 + c\gamma_l)$, where w is the bandwidth in Hertz and c is a constant depending on modulation scheme, symbol period, and target bit error rate (BER).

Different formulations for the power control problem have been studied, which can be generally categorized into two types: optimization and game theory approach. In the game theory approach, all links compete for limited radio resources, and the problem is formulated and solved as a noncooperative game in MacKenzie and Wicker (2001), where the solution is a Nash equilibrium power allocation, at which no link has incentive to unilaterally change its power. In contrast, the optimization approach assumes that all links update their powers for social welfare maximization in Lee et al. (2006), Tse and Viswanath (2005), and Chiang et al. (2007).

Efficiently solving the power control problem depends on whether the problem is convex or not. As convexity is long recognized as the watershed between easy and hard optimization problems (see Rockafellar 1993), the power control problem is often formulated as convex optimization, i.e., minimization of a convex objective function over a convex constraint set (see Lee et al. 2006; Tse and Viswanath 2005; Chiang et al. 2007; Foschini and Miljanic 1993; Hande et al. 2008). When the problem is formulated as nonconvex optimization (e.g., a discrete set of available power levels in Wu and Bertsekas 2001 and nonconvex objective functions in Yang et al. 2012; Qian et al. 2009), the problem becomes highly difficult to solve. For certain nonconvex cases, the problem can be still solved efficiently. For example, a log change of variables can turn an apparently nonconvex problem into a convex one as in the geometric programming approach that has been shown to solve a wide range of constrained power control problems in high SINR regime and a smaller set of problems in general SINR regime (see Chiang et al. 2007).

While convexity is the key to global optimality and efficient computation, decomposabil-

ity is the key to distributed solutions of the power control optimization problem. It is desirable to decompose the power control problem into subproblems with no communication overhead or message passing. In noncooperative game formulations of power control, distributed algorithms are naturally provided, such that each link can update its power by monitoring the total interference plus noise. In the optimization approach, various decomposition techniques, such as dual decomposition, primal decomposition, and penalty function method, can be used to decompose the original problem.

Key Applications

Fixed SINR The basic problem formulation for cellular network power control has been extensively studied, where transmit powers are the only variables, constrained by fixed target SINR γ_l and optimized to minimize the total power. To compute an optimal solution, the distributed power control (DPC) algorithm is proposed by Foschini and Miljanic in (1993), where the transmit power of link l is updated by $p_l(t+1) = \gamma_l p_l(t) / \text{SINR}_l(t)$, in which $t = 1, 2, \dots$, and $\text{SINR}_l(t)$ is the received SINR at the t th iteration. This algorithm is distributed as each link only needs to monitor its individual received SINR and can update its transmit power independently and asynchronously (see Yates 1995). It has been shown that this algorithm can achieve the optimal power allocation in the limit as t goes to infinity.

Variable SINR The fixed SINR approach is suitable for lightly loaded voice networks. When the network is heavily loaded, a wireless network needs to optimize the SINR assignment according to traffic requirements and channel conditions. Therefore, the problem becomes a joint SINR assignment and power control. In the vast research literature since the mid-1990s, solutions to this joint optimization problem are either distributed but suboptimal or optimal but centralized. For convex formulations of this problem, the work in Hande et al. (2008) develops

a distributed and optimal algorithm. The main idea is to reparametrize the complicated, and coupled constraint set into the so-called load-spillage representation, essentially a sophisticated change of coordinates, based on which the load-spillage power control (LSPC) algorithm has been developed such that each mobile user can compute an ascent search direction for this optimization problem locally. Convergence and optimality of this algorithm have been provided. Recently, LSPC has been adopted in the industry.

Future Directions

With the rapid increase of data service, the demand for higher data rate in wireless networks has been continuously increasing. Many wireless communication technologies have been developed, e.g., full duplex (FD) communication and device-to-device (D2D) communication, aiming to provide higher speed, larger capacity, and better QoS. At the same time, new challenges have been introduced. For example, FD communication will introduce strong self-interference, and D2D communication will interfere with not only the cellular communication but also the communication between other mobile devices. In the future, power control in wireless networks will focus on addressing these challenges, and it is expected that new modeling techniques, theoretical advances, and mathematical machinery will be required for these wireless and mobile applications.

Definitions

Grid discovery and diagnostics refers to characterizing both the electrical and topological properties of the grid and to monitor their evolution over time. It can be performed using two technical approaches. The first approach employs a series of electrical meters that are directly branched to the network and specifically designed to sense different electrical quantities.

The gathered information is then shared between the nodes or directly with a central unit using a separate communication device. The second approach exploits power line communications both as sensing and communication technology. Power line communications (PLC) transmitters generate signals according to their specific communication standard, while the receivers, apart from the classical communication function, exploit those signals to perform grid discovery and diagnostics. The sensing signals have a frequency range from few Hz to few kHz in the first approach, while in the second, as per PLC standards, the frequency range goes from few kHz to several MHz.

Historical Background

Grid discovery and diagnostics are traditionally performed using two separate devices. The first is a dedicated hardware, normally an electrical meter, that is branched to the grid and continuously senses the network. The second is a communication device endowed with a modem that is used to share the sensed data and possible control commands. The most common measurement device is called phasor measurement unit (PMU). Many PMUs are normally deployed across the grid and measure in a synchronized fashion the values of the main voltage and current about 30 times per second. When required, they can reach up to few thousand measurements per second. Concerning communications, there are different possibilities, including PLC, radio system, fiber optic, and satellite communications (Chairman et al. 2011). This monitoring system is well established in the context of high-voltage transmission networks and in wide medium-voltage distribution networks. However, conventional PMUs are not usually deployed in small-sized distribution networks or in micro-grids. In fact, given the average length of the power cables in such networks, frequencies higher than few kHz are preferable to efficiently perform grid discovery and diagnostics. In such networks utilities have a very low level of control.

For these reasons, a novel stream of research is proposing to use the high frequency of PLC to absolve discovery and diagnostic tasks in small-size grids. This has a double advantage. On one hand, with high frequency measurements, greater resolution can be obtained. On the other hand, since PLC are both used to monitor the network and to send communication signals, they embed in a single technology the role of sensors and modems. The idea is similar to what has been done for Internet access networks. In that context, digital subscriber line (DSL) modems have been used since the 1990s to monitor the “last mile” of telephone networks. The characteristics of power networks are, however, completely different, which requires a separate treatment.

Background on Grid Discovery

Grid discovery has emerged as a practical and research problem with the advent of convoluted and interconnected networks. The term refers to the ability of an ensemble of network nodes to infer the physical structure and the electrical parameters of the network. The nodes are enabled to discover their relative position within the grid, to detect the presence of other nodes, and, ultimately, to derive the grid topology. Furthermore, they are enabled to infer the electrical parameters of the cables, the impedance value of the loads, and the current and voltage at each termination. A complete knowledge of the structure of the grid allows utilities to optimize different aspects: the flow of the delivered power, the values of the balancing loads, the routing strategies of information signals for control, and the defensive strategies against possible intruders.

Grid discovery is normally treated as a state estimation problem based on the data provided by PMUs. The produced measurements are used in combination with state estimation algorithms to infer, depending on the application, different properties of the network (Huang et al. 2012). In transmission networks, it is of interest to estimate the voltage and current phasors at every node. In micro-grids, on the other hand, it is of interest to monitor the topological changes of the grid, since they occur too often to be manually controlled by an operator. Such techniques are always based on

complete or at least partial knowledge of the set of the possible topologies of the grid.

In recent years, interest has grown toward the inference of the topology of a distribution or micro-grid with no previous information about it. Some approaches, presented in the following, exploit high-frequency signals provided by PLC modems. Their use is of particular interest in medium- and low-voltage distribution networks, where the utilities have limited knowledge of the actual structure of the network.

Background on Grid Diagnostics

Grid diagnostics involve the constant monitoring of the grid with electrical signals in order to detect and possibly localize possible anomalies that might jeopardize the distribution of electrical power. Every consequent damage on the grid has to be repaired within the shortest time possible, in order to maintain a high service quality for the costumers. However, since transmission and distribution grids cover wide areas and they are often rather convoluted, detecting and localizing anomalies in a short time is a complex task. Given the huge economical and social impact that strong anomalies like short circuits can have, grid diagnostics have been performed on power grids since the beginning of the twentieth century. The proposed monitoring techniques have since then constantly evolved.

Grid diagnostics are typically based on power flow analysis (Grainger et al. 2016), and it focuses on the detection and localization of electrical faults. The basic technique consists of deploying one or more relays across the grid to monitor the delivered voltage and the total current absorbed by the loads. The presence of a fault is detected when the expected values of voltage and current exceed a predetermined threshold. The location of the fault is determined analyzing the phase of the fault current. Older systems exploited just mechanical relays that used fuses to detect overcurrents and trigger a circuit breaker. Modern microprocessor-enabled evolutions of these systems are still applied nowadays, especially in transmission networks (Das et al. 2014).

Along the years, more complex analysis techniques have been layered on basic threshold methods in order to detect and localize faults in topologically complex networks, to classify different kind of events, and to detect them even if they are very short or very weak (Shafiullah and Abido 2017; Sedighizadeh et al. 2010). Such techniques make use of various tools that can be broadly divided into deterministic and heuristic approaches. Deterministic approaches exploit time-domain or frequency-domain analysis applied to each new sensing event. Heuristic approaches, like neural or fuzzy networks and genetic algorithms, are based on training data and the available information about the grid. They are able to automatically detect and localize faults based on all the system history. Conversely from deterministic approaches, they require much more computation power, but they can better adapt to system changes.

In recent years, a lot of interest has grown toward diagnostics in underground grids and small-scale overhead grids which, as previously discussed, are not well controlled by the utilities. Given the small dimension of these grids, monitoring at high frequency is needed. For this reason, a series of methods that make use of PLC modems has been proposed not only to detect faults but also to track the aging of cables (particularly important in underground grids) and eventual changes of the loads. In the following, a description of these methods is presented.

Foundations

In order to optimize the communication rate, every communication protocol requires to perform channel estimation in order to apply equalization algorithms at the receiver. The channel is composed by the physical medium, the couplers, and the analog part of the transceivers. In the context of PLC, the medium is the power grid. If the couplers and the analog transceiver at the transmitter and at the receiver are well characterized, it is possible to estimate the medium transfer function (MTF). The MTF does not depend on the transmitted signals (although its estimation

depends on it), but it is an intrinsic property of the medium.

Each receiving modem can estimate the link transfer function (LTF) with respect to a transmitting modem. When the receiving modem starts a communication with another transmitter, then a new LTF is estimated, referring to the new link. If a modem is equipped with an impedance measurement circuit, it can also estimate the echo transfer function (ETF), i.e., from the transmitter modem to itself. Conversely from the LTF, the ETF is an intrinsic property of the node the modem is branched to.

The LTF and the ETF contain all the structural and electrical information about a specific power grid. The analysis of such information is based on the transmission line theory (Paul 2007; Passerini and Tonello 2018b). For example, from the time-domain ETF depicted in Fig. 1, it is possible to infer the following information. Each peak determines the position of a discontinuity in the grid, which might be a cable branch, a termination node, or even an anomaly. The amplitude of each peak is determined by the amount of the mismatch of the discontinuity with the line. This ultimately depends on the characteristic impedance of the power line and on the equivalent impedance of the load or the anomaly. Finally, the shape and the amplitude of the peaks depend on the electrical characteristics of the power line. Due to signal attenuation, frequency, and time spread, the access to this information is often limited, especially regarding the parts of the grid that are distant from the measurement point. For this reason, it is often preferred to fuse the information provided by the LTF of multiple links or the ETF of multiple nodes. Furthermore, the closer the nodes are to each other, the higher is the frequency bandwidth required to distinguish them.

Application: Grid Discovery

Three main approaches have been proposed to date to perform grid discovery, i.e., to estimate the grid topology. The first approach is based on reflectometry, that is, the estimation of the

Power Line Communications for Grid Discovery and Diagnostics, Fig. 1 Example of a time-domain ETF and associated information about the medium

echo signal from one modem deployed on a network termination. Assuming the presence of no anomaly, the peaks in the time-domain ETF unveil the presence of either branching points or terminations. Different algorithms have been proposed to emulate the peak sequence of the ETF by guessing node by node (Zhang et al. 2016) or peak by peak (Ahmed and Lampe 2012) the topology of the grid. This approach has the advantage of relying on just one measurement point, but the grid discovery is limited to few nodes next to it.

The second approach avoids peak analysis by operating on the data-link layer. A set of modems is deployed on all the grid terminations (Lampe and Ahmed 2013), or even on every node (Erseghe et al. 2013). Every modem has to establish a connection with each one of the others. During the handshake phase, the modem is capable of computing the round-trip time and, thus, to estimate the length of the link. When the length of all the possible links in the network is known, different algorithms based on decision and graph theories can be applied to infer the topology. This approach has the advantage of being scalable to high complex networks but requires an extensive deployment of broadband PLC modems.

The third approach relies on impedance measurements performed on the network nodes (Passerini and Tonello 2017). If the user has some

prior information about the cable parameters and the loads, it is possible to infer both the node-to-node distances and the topology in a unified algorithm by using the classical propagation equations from transmission line theory. This approach requires a lot of prior information and extensive deployment of PLC modems but can work both with wide-band measurements or using a single frequency down to few tenths of kHz.

A summary of the grid discovery methods using PLC is shown in Table 1.

Application: Grid Diagnostics

High-frequency grid diagnostics can be performed when at least one reference measurement, performed during the normal operation of the grid, is available. Then, the medium is continuously monitored, and every new estimation of the MTF is subtracted from or divided by the reference measurement, depending on the system model used (Passerini and Tonello 2018b), providing a test trace. Since the power line medium is periodically time variant in the 3 kHz–10 MHz range, using just one reference measurement would often provide non-null test traces. In order to discover anomalies, it has been proposed to analyze the features of the test traces with a machine learning algorithm. Such

Power Line Communications for Grid Discovery and Diagnostics, Table 1
Grid discovery methods using PLC

Method	Class	Advantages	Disadvantages
Reflectometry and model-based search	Echo	PLC modem on just one node, few prior information needed	Topology inference limited to few branches, requires wide band
Handshake and inference algorithm	Link	Scalable, few prior information needed	PLC modem on every termination or even on every node, requires wide band
Impedance	Echo	Single or multiple frequencies allowed, works also using low frequencies, cable length and connections in a single algorithm	Many parameters required, PLC modem possibly on every node

Power Line Communications for Grid Discovery and Diagnostics, Table 2
Grid diagnostics methods using PLC

Method	Class	Advantages	Disadvantages
Deterministic LTF	Link	Detection both close to the transmitter and the receiver	Ambiguity on the location
Heuristic LTF	Link	Detection both close to the transmitter and the receiver	Requires huge database, ambiguity on the location
Deterministic ETF	Echo	Reduced complexity algorithms, univocal localization	Detection only close to the sensing modem

algorithm has been tested to track the aging of underground cables, providing promising results (Förstel and Lampe 2017).

On the other hand, considering the periodicity of the channel variation as composed by a series of invariant states, it is possible to use an equal number of reference measurements. This way, if no anomaly is present, the amplitude and phase of the resulting trace is limited to a noise component. Every time a threshold set consistently to the average noise power level is exceeded, an anomaly is detected. This approach has been presented considering a single LTF or a single ETF (Passerini and Tonello 2018a), but of course the detection performance is improved when relying on measurements from multiple node or links. Different classification algorithms based on the features of the test trace can then be conceived to identify the type of the detected anomaly (Passerini and Tonello 2018a).

For what concerns the localization of an anomaly, it is performed by analyzing the test trace in time domain, and it mostly relies on

the knowledge of the network topology. When the topology of the grid is not known, it is only possible to retrieve the distance of the anomaly from a communication node, which corresponds to the position of the first peak in the time-domain MTF (either LTF or ETF). In the case of the ETF, the distance is univocally referred to the measurement point, but in the case of the LTF, an ambiguity is left, since the distance might be either referred to the transmitter node or to the receiver node (Passerini and Tonello 2018b). When the topology of the grid is known, then the precise branch where the anomaly takes place can be identified by a peak analysis of the test trace.

A summary of the grid diagnostic methods using PLC is shown in Table 2.

Definition

Utility functions are a mathematical representation of an individual's preferences for different goods and services.

Motivation

The notion of utility is motivated by a basic problem faced when allocating limited resources (such as bandwidth or power) to users of a wireless network: How should one account for differences in the users' needs for these resources? These differences can arise due to users running different applications that require different quality of service (QoS) levels or even for the same application due to differences in how users perceive changes in QoS. Moreover, modern wireless networks exist in evolving market structures with multiple competing firms using heterogeneous technologies. Understanding how this competition and the regulation around it impact end users again requires modeling user preferences for different services. The concept of utility is a way of providing a common metric

for representing such diverse needs. This idea has its roots in economics, where it is used for a similar reason, namely, to capture an individual agent's preferences for consumption of different allocations of goods or services (Mas-Colell et al. 1995). It is a central concept in economics and also widely used in game theoretic studies to model the payoffs of players in a game.

In the literature on wireless networking, utility functions are used in several distinct ways (Berry and Johari 2013). In some work these functions can be viewed as a semantic device used to explain the design and function of the distributed algorithms needed to operate these networks. In many cases these algorithms are such that the users of the network act as if they are optimizing some underlying utility. Here the choice of utility reflects the engineering decisions made when designing the algorithms. An example of such an approach is the use of utility functions to design different congestion control algorithms (e.g., Kelly 1997). This can contrast with work in which utility is used to capture the underlying economic preferences of the users of a network. In this case, the choice of utility is not an engineering decision but rather an attempt to model the incentives of actual users and so is much closer to the use of utility in economics. One example of this is work in the broad area of network economics (Huang and Gao 2013; Maillé and Tuffin 2014).

Preferences and Utility

In economics, utility functions are often defined in terms of an underlying *preference relation* for an agent. Suppose that there is a set X of possible outcomes available in a system, and let $\mathbf{x}$ denote a specific outcome. For example, if one is dividing a unit of bandwidth among a set of agents, X would indicate all possible divisions of this bandwidth, and $\mathbf{x}$ would indicate a specific division. A *preference relation*, $\succsim$, is a binary relation used to model a user's preferences for different outcomes so that if $\mathbf{x} \succsim \mathbf{y}$, then the user finds outcome $\mathbf{x}$ at least as "good" as outcome $\mathbf{y}$.

Generally, such preference relations are assumed to be rational as defined next.

Definition 1 A preference relation for an outcome set X is *rational* if it satisfies the following two properties:

1. *Completeness*: a preference exists between any two outcomes;
2. *Transitivity* if $\mathbf{x} \succsim \mathbf{y}$ and $\mathbf{y} \succsim \mathbf{z}$, then $\mathbf{x} \succsim \mathbf{z}$ for all $\mathbf{x}, \mathbf{y}$ and $\mathbf{z}$ in X .

A utility function is a way of representing a preference relation by assigning a numerical value (called the utility) to each possible outcome that is aligned with an agent's preferences.

Definition 2 A preference relation, $\succsim$, is represented by a *utility function*, $U : X \mapsto \mathbb{R}$, if $U(\mathbf{x}) \geq U(\mathbf{y})$ whenever $\mathbf{x} \succsim \mathbf{y}$.

In other words, a larger utility indicates that an outcome is more preferred by an agent. In some examples, the user's preferences and so their utility may depend only on a lower-dimensional function of the outcome; for example, in the case of resource allocation in networks, a user's utility may be a function only of the total rate allocation they receive, in which case one often writes the utility as only depending on this lower dimensional quantity.

Representing a preference relation by a utility requires that the preference relation be rational as stated next.

Proposition 1 A preference relation can be represented by a utility function only if it is rational.

If the underlying outcome set is finite, then the necessary condition in Proposition 1 is also sufficient, i.e., any rational preference relation over a finite set of outcomes can be represented via a utility. However, if the outcome set is infinite, this need not be true (but will be true under additional continuity assumptions; see e.g., Mas-Colell et al. 1995.) Conversely, it can be shown that any utility function defined over a set of outcomes gives a rational preference relation.

The assumption of rational preferences leads to an appealing mathematical framework and is widely used. However, it is not without controversy and, in particular, is not fully supported by experimental studies. This in turn has led to interest in a range of alternative ways of modeling preferences such as models for bounded rationality (Rubinstein 1998).

Comparing Utilities

Ordinal Utility

For a utility to represent a preference relation as in Definition 2, only the *relative* ranking of the utilities matters and not the *absolute* numeric values of the utility. In other words, whether an agent prefers $\mathbf{x}$ to $\mathbf{y}$ only depends if $U(\mathbf{x})$ is larger or smaller than $U(\mathbf{y})$. For this reason such a utility function is referred to as an *ordinal utility*. Note that as a consequence, the ordinal utility representing an agent's preferences is not unique. Indeed, if we set $V(\mathbf{x}) = f(U(\mathbf{x}))$ for any strictly increasing function f , then $V(\mathbf{x})$ is another valid utility function that represents the same preferences as $U(\mathbf{x})$.

Pareto Efficiency

Ordinal utility suffices for representing the preferences of one agent. However, one would often like to compare outcomes for a group of agents. The notion of Pareto efficiency (also called Pareto optimality) provides one basic way of doing this.

Consider a situation in which there are N agents impacted by the choice of outcome from the set X . Each agent i 's preferences are represented via a utility $u_i(\mathbf{x})$.

Definition 3 An outcome $\mathbf{x}$ in X is *Pareto efficient* if there is no other outcome $\mathbf{y}$ so that $U_i(\mathbf{y}) \geq U_i(\mathbf{x})$ for all agents i and this inequality is strict for at least one agent j .

In other words, for an outcome to be Pareto efficient, there must be no way to improve the outcome for one agent without making the outcome worse for other agents. Pareto efficiency provides a baseline notion of efficiency but in

many cases does not lead to a unique choice of outcomes. For example, suppose that there is a single (indivisible) good to be allocated to one of N agents. Each agent strictly prefers getting the good to not getting it; if an agent does not get the good, she is indifferent between which other agent gets it. Allocating the good to any agent is then Pareto optimal. To choose a particular one of these outcomes, it is natural to ask which agent values the good the most, i.e., which agent receives the "most utility" from the good. Without additional assumptions, an ordinal utility does not allow us to answer such questions. Since the units of utility have no meaning, it is not possible to make comparisons across agents.

When faced with multiple Pareto optimal outcomes, various *fairness* notions may be used to decide on one of them. A key distinction here is that Pareto optimality is an objective notion for characterizing a "good" outcome, while fairness is inherently subjective. Alternatively, one can make further assumptions on utility functions that facilitate comparisons. The class of quasilinear utilities described next provides one way of doing this.

Quasilinear Utilities

A common approach to facilitate comparisons across utility functions is to introduce money into the model and assume that the agents have preferences which are linear in their amount of money.

In such a setting, the set of outcomes X can be expanded to include monetary transfers, i.e., if there are N agents participating in the system, an outcome will now be given by $(\mathbf{x}, \mathbf{m})$ where $\mathbf{x}$ is again an outcome from X and $\mathbf{m} = (m_1, m_2, \dots, m_N)$ is a vector denoting the money m_i allocated to each agent i . Under a quasilinear utility model, each agent i 's net utility for this outcome are then given by

$$u_i(\mathbf{x}) + m_i,$$

where $u_i(\mathbf{x})$ indicates agent i 's value for the outcome $\mathbf{x}$. The quasilinear assumption means that we can view the valuation $u_i(\mathbf{x})$ for each agent i as being measured in monetary units; i.e.,

this represents the amount of money an agent is willing to pay for the given outcome (because of this, the quantity $u_i(\mathbf{x})$ is sometimes referred to as an agent's *willingness to pay*).

Quasilinear utilities are often assumed in the literature, in particular, in cases where market-based mechanisms are used to decide on an outcome (in which the consideration of money is natural). This assumption greatly simplifies analysis. Indeed, many key results in areas such as mechanism design or welfare economics are based on quasilinear utilities. For example, it leads to a much simpler characterization of Pareto efficient outcomes as shown in the next theorem.

Theorem 1 *Suppose all users have quasilinear utility and that any monetary allocation is allowed that satisfies $\sum_i m_i \leq 0$. Then an allocation $(\mathbf{x}^*, \mathbf{m}^*)$ is Pareto optimal if and only if it satisfies the following two conditions:*

$$\mathbf{x}^* \in \arg \max_{\mathbf{x} \in X} \sum_i U_i(\mathbf{x});$$

$$\sum_i m_i^* = 0.$$

One can view this as a situation where each agent initially has no money; agents are allowed to transfer money to other agents with no credit restrictions. The constraint $\sum_i m_i \leq 0$ means that money may leave the system but no external money can be added. The result then shows that at a Pareto optimal allocation, the sum of these transfers will be zero. Essentially, one can use monetary transfers to compensate any agent for a loss of utility that leads to an overall increase in the total utility.

Because of this result, in quasilinear environments, Pareto optimality corresponds to maximizing the sum of the valuations across the users. This sum is often referred to as the *social welfare* of the allocation. However, quasilinearity is a strong restriction on user preferences that is not supported in all scenarios. For example, this does not apply to settings in which agents exhibit a “wealth effect,” meaning that they are willing to pay more for an item when they have more money available.

Expected Utility

Utilities can also be used when there is uncertainty in the outcome. Such uncertainty is often modeled by assuming that under a given decision, outcomes in a set X occur with a given probability distribution also referred to as a *lottery*. For example, if there are only two possible outcomes, $\mathbf{x}_1$ and $\mathbf{x}_2$, then a lottery $p = (p_1, p_2)$ would indicate that outcome $\mathbf{x}_i$ occurs with probability p_i . Let $\mathcal{P}$ denote the set of all lotteries over a given outcome set X , e.g., for our two outcome example:

$$\mathcal{P} = \{(p_1, p_2) : p_i \geq 0 \text{ and } p_1 + p_2 = 1\}.$$

Agents can then be viewed as having a preferences over lotteries, modeled via a preference relation $\succsim$ over $\mathcal{P}$.

Given two lotteries p and p' over a given set of outcomes, one can combine them to form a new lottery by using lottery p with probability α and lottery p' with probability $(1 - \alpha)$. Such a compound lottery is denoted by $\alpha p + (1 - \alpha)p'$. Using this notion, the following two properties of a preference over lotteries can be defined.

Definition 4 A preference relation $\succsim$ over $\mathcal{P}$ is *continuous* if given any three lotteries p , p' , and p'' with $p \succsim p' \succsim p''$, there exists a probability α so that the lottery $\alpha p + (1 - \alpha)p''$ is equivalent to p' .

Definition 5 A preference relation $\succsim$ over $\mathcal{P}$ satisfies *independence* if for any three lotteries p , p' , and p'' , $p \succsim p'$ if and only if $tp + (1 - t)p'' \succsim tp' + (1 - t)p''$ for any probability t .

The most common way of using utility functions to represent such preferences is via an expected utility representation as defined next.

Definition 6 A preference relation $\succsim$ over the lotteries $\mathcal{P}$ on a set of outcomes X has an *expected utility representation* if there exists a utility function $u : X \mapsto \mathbb{R}$ such that if $p \succsim q$ then the expected utility under p is no smaller than that under q .

In other words, if a preference has an expected utility representation, then one only needs to define a utility function over the underlying set of outcomes and not directly on the space of lotteries over these outcomes. Lotteries are then compared by taking the expected value of this utility.

For a preference to have an expected utility representation, this relation again needs to be rational. However, this is not sufficient. A fundamental result from von Neumann and Morgenstern (1955) shows that a rational preference over a finite set of outcomes has an expected utility representation if and only if it is also continuous and independent (again this can be extended to infinite sets of outcomes with some additional technical assumptions). Such a utility function is also referred to as a *von Neumann-Morgenstern utility*. When studying decision-making under uncertainty, von Neumann-Morgenstern utilities are typically assumed. However, it should be noted that as with rational preferences, this assumption is again not supported by many experimental studies. Alternatives have been developed to better capture some characteristics of observed human behavior, such as *prospect theory* proposed in Kahneman and Tversky (1979).

Divisible Resources

In many networking problems, the underlying outcome can be viewed as a continuous nonnegative quantity x that is allocated to a given agent. For example, x could represent the amount of some resource allocated to a given agent, where we assume that this resource is perfectly divisible. In such a setting, we can view an agent's utility as a function defined on the positive real line (or some subset of it). In such contexts there are two other properties of utility functions that are natural to consider.

Monotonicity. Often one only considers utility functions that are nondecreasing in the allocation x . This means that every individual prefers more resources to less resources. A key implicit reason that monotonicity is plausible is the notion of

free disposal: that excess resources can always be “disposed of” without any cost or penalty. With free disposal, an individual is never worse off with additional resources.

Concavity. Utility functions can take any shape or form, but one important distinction is between *concave* and *convex* utility functions. Concave utility functions represent diminishing marginal returns to increasing amount of resource, while convex utility functions represent increasing marginal returns to increasing amount of resource.

In the context of network resource allocation, there is an additional interpretation of concavity that is sometimes useful. Consider two users with the same utility function $U(x)$ as a function of a scalar data rate allocation x ; these users share a single link of unit capacity. We consider two different resource allocations. In the first, we randomly allocate the entire link to one of the two users. In the second, we split the link capacity equally between the two users. Which scenario do the users prefer?

Observe that if the users are making a phone call which requires the entire link for its minimum bit rate, then the second scenario is undesirable. On the other hand, if the users are each downloading a file, then the second scenario delivers a perfectly acceptable average rate (given that both users are contending for the link). The first (resp., second) case is often modeled by assuming that U is convex (resp., concave), because the expected utility to each user in the first allocation is *higher* (resp., lower) than the expected utility to each user in the second allocation. (Both results follow by Jensen's inequality.) For this reason, concave utility functions are sometimes thought to correspond to *elastic* traffic and applications, such as file-sharing downloads, while convex utility functions are often used to model applications with *inelastic* minimum data rate requirements, such as voice calls.

Finally, from a technical standpoint, we note that concavity plays an important role when we consider maximization of utility, given the technical simplicity of concave maximization problems.

Risk Aversion

The discussion of inelastic and elastic utility functions above is closely connected to the notion of *risk aversion* in economic modeling. To see the connection, suppose $U(w)$ represents an agent's utility for w units of currency (or wealth). Suppose the individual is offered a choice between W units of wealth with certainty or a gamble that pays zero with probability $1/2$ or $2W$ with probability $1/2$.

Note that the same kind of reasoning as above reveals that if U is concave, then the individual prefers the sure thing (W units of wealth with certainty), while if U is convex, the individual prefers the gamble. For this reason we say that an individual with concave utility function is *risk averse*, while an individual with a convex utility function is *risk seeking*. It is generally accepted that individuals tend to be risk averse at higher wealth levels and risk neutral (or potentially even risk seeking) at lower wealth levels.

Principle of OFDM and Multi-carrier Modulations

Hao Li

Department of Electrical and Computer Engineering, The University of Western Ontario, London, ON, Canada

Synonyms

[Multi-channel modulation](#); [Multi-tone modulation](#); [Orthogonal FDM](#)

Definitions

Orthogonal frequency division multiplexing (OFDM) is a transmission technique that divides the whole bandwidth into many subchannels that are closely spaced with overlapping spectra and mutually orthogonal to each other, and transmits a number of parallel low-rate data streams that are split from a higher-rate serial data stream over these orthogonal subchannels simultaneously.

Multi-carrier modulation (MCM) is a transmission technique that divides the whole bandwidth into many subchannels, without a specific orthogonality requirement, and transmits multiple data streams in parallel over the subchannels. OFDM is a special form of MCM.

Historical Background

The development of OFDM dates back to 1950s when the initial MCM system was developed for the military high-frequency (HF) radio links (Dolez et al. 1957; Mosier and Clabaugh 1958). The original MCM systems, which transmitted parallel data streams over nonoverlapped channels separated by steep-sided filters, suffered low spectrum efficiency and high implementation complexity. To overcome these challenges, a number of efforts have been dedicated to achieve MCM with overlapped channels in the 1960s. In 1961, Franco and Lachs proposed a multi-tone, code-multiplexing scheme (Franco and Lachs 1961), in which sine and cosine waves were used to generate orthogonal signals. The concept of OFDM was first introduced by Chang in 1966 (Chang 1966). Fourier transform was exploited to produce orthogonality between the subchannels over a band-limited channel. In 1967, Saltzberg extended Chang's work to complex data and proposed staggered QAM technique to reduce cross talk between adjacent channels (Saltzberg 1967). The orthogonality of subchannels in the analog OFDM system was preserved when the number of subcarriers was not large.

A digitally implemented OFDM system was first introduced by Weinstein and Ebert in 1971 (Weinstein and Ebert 1971), in which the discrete Fourier transform (DFT) was proposed to generate orthogonal subcarriers at the transmitter. This DFT-based OFDM totally eliminated bank of subcarrier oscillators at the transmitter/receiver, so as to reduce the implementation complexity. Another milestone in OFDM came in 1980, when Peled and Ruiz introduced a cyclic extension to the OFDM signal (Peled and Ruiz 1980), which is more commonly referred to as cyclic prefix (CP) today. The CP effectively turns the linear convolution of a multipath channel into circular convolution, which can eliminate inter-symbol interference (ISI) and ensure orthogonality over a time dispersive channel as long as the CP is longer than the impulse response of the channel.

OFDM gained much more popularity and attentions after the introduction of DFT and CP. Many works in the 1980s suggested the

use of OFDM for high-speed moderns and digital mobile communication systems. In 1985, OFDM was first applied in mobile wireless communications by Cimini (1985). In the late 1980s, the work began on the development of OFDM for commercial use. The first OFDM-based standard Digital Audio Broadcasting (DAB) was ratified in 1995 (DAB 1995). Since then, OFDM has been adopted in many wireless communication standards applied to wireless personal area networks (WPAN), wireless local area networks (WLAN), and wireless metropolitan networks (WMAN). In parallel to the commercial development, techniques to improve the performance of OFDM in different channel environments and diverse applications were also developed, such as time and frequency synchronization (Wang et al. 2003), peak-to-average power ratio (PAPR) reduction (Wang et al. 1999), and transmission security enhancement (Li et al. 2015).

Foundations

The principle of OFDM and MCM is illustrated in Fig. 1. Compared with the conventional single-carrier modulation that transmits a data stream serially over one radio frequency (RF) channel, MCM divides the RF channel into multiple subchannels and transmits multiple data streams over them in parallel. As a special form of MCM, OFDM divides the entire channel into many narrowband flat-fading subchannels that are orthogonal to each other, splits the serial data stream in parallel, and then transmits these parallel data streams simultaneously over the orthogonal subchannels with a one-to-one correspondence. A time-domain OFDM signal with N subchannels (which are also called subcarriers) can be expressed as

$$x(t) = \sum_{k=0}^{N-1} X(k)e^{j2\pi f_k t}, \quad 0 \leq t \leq T, \quad (1)$$

where $X(k)$ is the data stream transmitted on the k th subcarrier and T is the duration of an OFDM

Principle of OFDM and Multi-carrier Modulations, Fig. 1

Comparison of single-carrier modulation, multi-carrier modulation, and OFDM

signal. $f_k = k\Delta f$ is the frequency of the k th subcarrier, where Δf is the subcarrier spacing and $T\Delta f = 1$.

With a sampling interval of $T_s = \frac{T}{N}$, the sampled version of the OFDM signal $x(t)$, denoted as $x(n)$, can be given by

$$x(n) = \sum_{k=0}^{N-1} X(k) e^{j2\pi f_k \frac{nT}{N}}, \quad n = 0, 1, \dots, N-1. \quad (2)$$

Substituting $f_k = \frac{k}{T}$ into (2), the above equation can be rewritten as

$$\begin{aligned} x(n) &= \sum_{k=0}^{N-1} X(k) e^{j2\pi \frac{k}{T} \frac{nT}{N}} \\ &= \sum_{k=0}^{N-1} X(k) e^{j2\pi \frac{kn}{N}}, \quad n = 0, 1, \dots, N-1. \end{aligned} \quad (3)$$

It can be found that (3) is exactly the expression of inverse discrete Fourier transform (IDFT) of $X(k)$. Therefore, the OFDM modulation process can be effectively implemented by using IDFT

or even a more efficient algorithm inverse fast Fourier transform (IFFT) of reduced computational burden. Figure 2 provides an illustration of an OFDM signal with five subcarriers, where Fig. 2a represents the construction of the time-domain OFDM signal and Fig. 2b depicts how the OFDM signal looks like in the frequency domain.

To deal with the time dispersion of wireless channels, a CP is generally employed in each OFDM signal. The basic idea of CP is to repeat the end part of a time-domain OFDM signal in its beginning to create a guard period between adjacent OFDM signals. As long as the duration of CP is longer than the maximum excess delay of the wireless channel, the ISI corrupted part of an OFDM signal stays within the guard period and can be removed later at the receiver. Hence, the impact of multipath distortion on the orthogonality among the OFDM subcarriers can be removed. Figure 3 demonstrates the principle of ISI elimination in OFDM using CP.

In addition to the spectrum efficiency achieved by the 50% overlapping between subchannels, OFDM is more robust against multipath propagation in comparison with the single-carrier system. OFDM has a larger symbol duration since the data stream is now split and transmitted in par-

Principle of OFDM and Multi-carrier Modulations, Fig. 2
 Illustration of an OFDM signal with five subcarriers

Principle of OFDM and Multi-carrier Modulations, Fig. 3 ISI elimination in OFDM using cyclic prefix

allel with a lower data rate on the orthogonal subchannels. This makes the transmission resilient to ISI and inter-frame interference. By dividing the overall frequency-selective fading channel into multiple narrowband subchannels, each subchannel is now affected individually as a flat-fading channel. Also, channel estimation and equalization can be easily applied on these flat-fading subchannels. Moreover, interference appearing on a channel could be bandwidth limited so that only data on part of the subchannels would be

affected in OFDM transmission. However, it is also noteworthy that synchronization error could destroy the orthogonality of OFDM subchannels and then disturb the transmission. OFDM thus requires highly accurate time and frequency synchronization. In addition, an OFDM signal could have a high PAPR, as it is a superposition of a large number of statistically independent symbols transmitted on all its subchannels. The signal peaks need to be mitigated in the practical implementation.

Key Applications

As an attractive transmission technique of high spectrum efficiency and robustness to channel fading, OFDM has been employed by various existing and evolving standards and products. It has been widely exploited in wired communications like digital subscriber line (DSL) and digital cable TV transmission. Also, OFDM is used as the transmission technique by powerline devices to provide high-speed local area networking over existing power lines. Meanwhile, OFDM has been adopted in major wireless communication standards, including European DAB; worldwide terrestrial digital video broadcasting like DVB-T, T-DMB, and ISDB-T; as well as 4G mobile phone standards 3GPP long-term evolution (LTE) and LTE-Advanced. Moreover, OFDM has been approved or considered by many IEEE standard working groups, such as IEEE 802.11a/g/n/ac/ax/ad/ax for WLAN, IEEE 802.15.3a for WPAN, IEEE 802.16 for WMAN, IEEE 802.20 for mobile broadband wireless access (MBWA), and IEEE 802.15.7 for visible light communication. In addition, OFDM is being investigated as one of the most promising radio transmission techniques of the 3GPP 5G wireless networks (Farhang-Boroujeny and Moradi 2016).

Game theory based privacy preservation; Privacy
attack and defense game

Definition

In general, privacy game can be defined as individual and/or cooperative behaviors between the user and the adversary (attacker) that choose a certain defense/attack strategy/action to maximize their self-interest.

Take Stackelberg privacy game (Shokri 2015; Shokri et al. 2012) between the user and the adversary as an example. The user plays first by choosing a privacy protection mechanism and committing to it by running it on his or her actual data. The follower (adversary) plays next by inferring the user's data, knowing the protection mechanism that the user has committed to. Specifically, the Stackelberg privacy game is defined as:

1. Nature selects a data (i.e., user secret that contains privacy information) for the user, where the data are selected according to a probability distribution function.
2. Given the chosen data, the user runs a protection mechanism to generate a disguised data (subject to some constraints predetermined) to release.
3. Having observed the released data, the adversary selects an estimated data by inference function. The adversary knows the internal implementation and the user's data probability distribution.

4. The adversary pays an amount (often represented by inference error equivalent to the privacy gained by the user) to the user.

In such a game, both the user and the adversary aim to maximize their payoff, i.e., the adversary tries to minimize the amount he will pay, while the user tries to maximize it. That is, they form a game-theoretic equilibrium, which is a solution for a privacy game.

Historical Background

Game theory acts as a mathematical tool used to describe and solve games (Liang and Xiao 2013). In many cases, privacy can be achieved through cooperation among entities. Users should evaluate their privacy themselves and investigate different strategies to set their privacy at their chosen level. Some researchers began to try to employ game theory – a mathematical tools for multiplayer strategic decision making – to model the interactions of agents in privacy problems. Furthermore, the theory of mechanism design (Nisan and Ronen 1999; Nisan 2007) has enabled researchers to design privacy protection mechanisms based on the analytical results (e.g., equilibrium analysis of the game). Attack and defense decisions arrived at using such game-theoretic approaches help to allocate limited resources, balance perceived risks, and take into account the underlying incentive mechanisms (Manshaei et al. 2013).

Typical Applications

According to Manshaei et al. (2013), we summarize typical applications as follows.

1. Location Privacy

Freudiger et al. (2009) first present a user-centric location privacy model to capture the evolution of location privacy for each user over time. The model considers the beliefs of users

about the tracking power of the adversary, the amount of anonymity that users obtain in the mix zones, the cost of pseudonyms, and the time of changing pseudonyms. A static game is defined where the players are mobile nodes. Each player has two strategies: Cooperate and thus change her pseudonym at mix zones, or Defect. The payoff can be calculated using the user-centric location privacy model.

2. Economics of Anonymity

Anonymity and privacy cannot be obtained by individual senders or receivers. The users should trust the infrastructure to provide protection, and other users must use the same infrastructure as well. Acquisti et al. (2003) explore the incentives of participants to offer and use anonymity services with a game-theoretic approach. They analyze the economic incentive for users to send their messages through mixnets (Chaum 1981).

3. Trust Versus Privacy

Network nodes need to disclose some private information in order to establish trust. This causes a tension between security and trust in networks. Using a game-theoretic approach, Raya et al. (2010) study this trade-off. They model the strategies of rational users that try to establish data-centric trust in the presence of rational adversaries.

4. Miscellaneous

Zhang et al. (2010) address the problem of defending against entry-exit linking attacks in Tor (The Onion Routing) network using a game-theoretic approach. They formalize the problem as a repeated noncooperative game between the defender and the adversary. They extract three design principles, namely, stratified path selection, bandwidth order selection, and adaptive exit selection, by using the results of the game between attacker and defender. Using these results, they develop gPath, a path selection algorithm that integrates all three principles to

significantly reduce the success probability of linking attacks in the Tor network.

Location based services; Privacy preservation

Definitions

The Location-Based Services (LBS) are information, alerts, or entertainment services that are provided to users according to their geographical and temporal information. Examples of LBS include location-based traffic reports, store finder, advertisements, and entertainments.

Historical Background

With the popularity of location-detection devices (e.g., handled devices equipped with GPS), their holders benefit a lot from LBS applications by receiving specific and useful information based on their location data. As a result, LBSs gain a dramatic development recently and various LBS applications have appeared. According to Shengling et al. (2018), LBSs can be classified into two categories, that is, elementary services and derivative services. Two typical examples of elementary services are navigation and search of Points of Interest (POIs). In navigation, positioning systems embedded in vehicles or handled devices can provide the location data

of their users, and these data are utilized by LBS applications to offer guidance for the users. This kind of services is the foundation of the main functions of Google Maps, Baidu Map, and AutoNavi Map. With respect to the search of POIs, a user can be recommended with the places nearby that he is interested in. Typical applications of such kind of services include Yelp, AroundMe, and Dianping. Atop these elementary services, various derivative ones, like mobile commerce, location-based games, and solomo applications, have come up to provided more complicated services. Besides these two kinds of applications, the location information can be also utilized to construct session keys for private communications (Zi et al. 2017).

Obviously, LBSs have brought much convenience to people's daily life. However, a lot of sensitive information can be disclosed by the process of collecting and analyzing the locations and queries of the users. For example, when a user queries the LBS server for the nearest restaurant from him, the server can obtain the accurate location of this user at this time. If the user queries the server consequently for different services, the trajectory of this user can be inferred by the server. This trajectory might be utilized by the server to send specific advertisements to this user that makes him bored. Situations become much worse when the location information of the users is obtained by the thieves as this kind of information indicates whether this user is at home. As for the queries, they might expose some private information of the user, like his behavior patterns or preferences. In this sense, how well the privacy of the users can be preserved determines the mass market share of LBS.

Foundations

Related to privacy preservation for LBS users, a great number of works focus on how to preserve the location privacy. These works can be categorized to three types, that is, k -anonymity,

cryptography-based oblivious data search, and differential privacy-based approaches.

- ***k*-anonymity.** This is the most popular method to preserve the location privacy of LBS users. The basic idea is that the location perturbation of a certain user is achieved with other $k - 1$ users. In this manner, *k*-anonymity can make the probability of exposing a host user's location less than $1/k$. The direct application of *k*-anonymity is proposed in Haibo and Jianliang (2009) where the proximity information of a certain LBS user is used to construct a cluster with other $k - 1$ users in a peer-to-peer manner. In this way, the cloaking area is the one that is covered with the newly constructed cluster. As the method in Haibo and Jianliang (2009) is time-consuming, a real-time location anonymization algorithm is presented in Joseph and Romit Roy (2009) by introducing the concept of prediction privacy. Since it is very possible that the adversary can have side information about the user's real location, the authors of (Ben et al. 2014) design an entropy-based measure to achieve *k*-anonymity.

- **Cryptography-based oblivious data search.** In Roman et al. (2015), identity-based encryption and hash encryption are combined to construct a private information retrieval method to secure the location privacy of LBS users. Since the somewhat homomorphic encryption (SHE) schemes become much easier to be implemented and run much faster, another kind of method is to encrypt the location data under SHE schemes. The nearest services can be computed based on the encrypted data (Anh et al. 2017). This is like to find *k* nearest neighbors over encrypted data in Wai Kit et al. (2009) and no other parties except the user himself can obtain the original location data.

- **Differential privacy-based approaches.** The location privacy of the differential privacy-based approaches is achieved via adding noises to original location information. In this way, geo-indistinguishability with no loss of LBS quality is able to be satisfied (Miguel et al. 2013). Usually, these approaches apply Laplacine noise to perturb a user's location, which is the

most typical way of realizing differential privacy (Shengling et al. 2018).

Apart from location information, the queries also contain important but sensitive information about the LBS users. However, the works address query privacy are much fewer compared with the ones aiming to preserve location privacy.

To preserve the query privacy, related methods are classified into identity hiding and content hiding. Hiding identities of the LBS users means that it is impossible to link any query to a certain user. In Bugra and Ling (2008), a personalized *k*-anonymity model is proposed to guarantee the specialized anonymity level that the users desire where the spatial and temporal tolerance of a cloaking area is taken into consideration. Because the model in Bugra and Ling (2008) relies on a fully trusted anonymizer, there is a great risk that all the identities might be disclosed if the anonymizer is compromised by attackers. To address this issue, a distributed algorithm to achieve *k*-anonymity in a peer-to-peer manner is proposed in Chi-Yin et al. (2011). As stated in Lichuan et al. (2018), only hiding the identities is fragile to tracing attack by some side information. This leads to the necessity to hide the content of queries in the meanwhile. When hiding the content of the query, it means that the attributes of the queries should be hidden. One direct way is to generate several dummy queries to be sent to the LBS server at the same time (Aniket et al. 2011). By this manner, the actual query is undistinguishable from all the other queries. The main drawback of this method is introducing too much communications overhead. Also, some cryptographic techniques are also proposed. By utilizing oblivious transfer to map the private location of the user to a public cell, a query-hiding framework is proposed in Russell et al. (2013).

Future Directions

Although different countermeasures have been proposed to preserve the privacy of LBS users, the following open issues are still needed to be further explored.

• **Designing lightweight privacy preserving methods:** As smart handled devices with limited energy are prevalent nowadays, it is required to work out lightweight privacy preserving methods for LBS users. This is because additional computation and communication overhead would be introduced in the process of preserving both location and query privacy. The situation becomes much worse when complex cryptographic approaches are utilized. In order to save the energy of batteries, it is very possible for LBSs users to give up applying these energy-consuming methods.

• **Preserving location and query privacy simultaneously:** Through the analysis in Foundations, most existing works address either location privacy or query privacy. Actually, these two categories are not independent. Only focusing on one aspect means the other one would be the side information to infer the private information of LBS users. Thus, there is an urgent need to work out new methods to preserve location and query privacy simultaneously.

• **Detecting the misuse of LBSs when preserving privacy beforehand:** Preserving privacy means that it is impossible to link a location or a query to a certain user. Motivated by financial interests, some users might misuse LBSs and only preserving privacy encourages these malicious users to keep their misuse without being detected. To deal with the conflicting issues of preserving privacy and detecting misuse, new privacy preserving methods that are capable of privately proving the reliability of LBS users should be put forward.

Data gathering and aggregation with privacy preservation in smart grids; Privacy-preserving data integration for the modernized power grid

Definitions

Privacy-preserving data aggregation (PPDA) in smart grids is the compilation of the local smart meter measurements with the intent to prepare aggregated power consumption for the control and optimization in the operation center under the privacy guarantees. PPDA in smart grids can also be interpreted as the process where raw data of smart meters is gathered and expressed in a summary form for statistical analysis without the leakage of each consumer's sensitive information.

Historical Background

Integrated with demand response, renewable energy resources, information technologies, and etc., the smart grid has become a key technology to upgrade and modernize the traditional power

grid. The terminology named smart grids was defined by the Energy Independence and Security Act in 2007, and it has received much attention from governments, industries, and researchers. With numerous smart meters and advanced monitoring systems, data aggregation is becoming a significant step to achieve efficient, stable, and secure operation of power systems. For example, the operation center needs to collect electricity consumption information for efficient power dispatch through the aggregation of smart meter measurements from end users. Meanwhile, local aggregators may interact with neighbors to obtain the aggregated information in a distributed way, which is more promising for the lightweight computation and communication, and the privacy concern. Many results have shown that the privacy of end users can be disclosed through smart meter readings. In 1992, Hart et al. investigated the power consumption identification of each household electric appliance by eye inspection of readings (Hart 1992). Then, a sequence of nonintrusive appliance load monitoring analysis technologies based on aggregated measurements in smart grids were studied (Zeifman and Roth 2011). The Website bwired.nl created by a Dutch student also shows the sensitive data disclosure of the consumer through the smart meter measurements. By exploiting the sensitive data, the privacy of the consumer, including preferences, habits, behaviors, and even beliefs, can be obtained. As a result, property and mental losses are caused to the customer. For instance, the theft may be able to sneak into an empty house or the attacker can use the private information to hack into the computers. These privacy concerns impede the development and implementation of the smart grid. For instance, due to the privacy rights, the Dutch Parliament turned down the bill for smart grid deployment in 2009. In order to preserve privacy in data aggregation, in past years, different solutions have been investigated (Garcia and Jacobs 2010; Rial and Danezis 2011). On the one hand, the investigation on the centralized PPDA has been done, where the local load perturbation based on

the storage or controllable load and the secure data transmission based on cryptographic theory were studied (Sun et al. 2018). On the other hand, much attention has been paid to distributed PPDA in smart grids, such as the privacy-preserving consensus-based energy management protocol (Zhao et al. 2017).

Foundations

Originally, aggregation is developed to deal with the computation overhead and resource allocation issues caused by the limited storage and complex analysis for the bulk quantities of measurement data. In the smart grid, PPDA aims to analyze the statistical information of the huge volumes of smart meter measurement data, including the sum of the power consumption of end users, the average or maximum (minimum) expending, and etc., while preserving the sensitive information of the end users. From the perspective of end users, there are two potential approaches of preserving privacy in the data aggregation. The first approach is the local data perturbation method where the data is perturbed before sending to the utility company. Storage devices or controllable loads, i.e., the local rechargeable battery, electric vehicles, heating, ventilating, and air conditioning (HVAC) systems, etc., are utilized to obscure the actual household energy consumption that is measured and reported by the smart meter (Sun et al. 2018). These solutions are customer-oriented, which are more desirable to accommodate individual privacy preferences. Existing schemes are described as below:

- **Battery-based load hiding (BLH) schemes:** BLH methods enclose the electricity utilization variations through regulating the charging and discharging process of the battery. The household load profile variances can be adjusted with a rechargeable battery to keep a constant output. Differential privacy and information leakage are applied to characterize the privacy-preserving degree. Such methods can be very costly to implement.
- **Load-based load hiding (LLH) schemes:** LLH methods achieve the load masking by shifting

the user's controllable loads. Under the proposed schemes, either the energy consumption is flatten over time or artificial electricity signatures are injected to hide the original load profile. Available options for the controllable loads are very limited for LLH schemes.

- **BLH-LLH schemes:** BLH-LLH methods combine BLH and LLH by exploiting both of household controllable loads and local batteries and thus to render the power consumption preservation more practical in the implementation stage.

The other approach is to preserve the privacy during the data aggregation process, which happens after the smart metering readings are broadcast. We introduce commonly used methods as follows:

- **Data anonymization:** data anonymization methods remove the attribute information from the meter readings to obscure the correspondence between smart meters and customers. However, these methods may fail when the side information of users is attainable.
- **Cryptographic-based computation (CBC) methods:** CBC schemes apply the homomorphic encryption and secret sharing, masking and brute forcing, modified homomorphic encryption, and so on, so that the aggregator cannot know the sensitive information in the measurements, while the aggregated results can be decrypted by the utility company. These methods are limited by their required computation or communication complexity, and the performance depends on specific model design with respect to the privacy protection.
- **Random noise adding (RNA) methods:** RNS schemes hide the power consumption by adding random noise to the real data. For example, differential privacy has been a hot research topic and applied in practical data integration process. It aims to maximize the accuracy of queries from statistical databases while maintaining indistinguishability of its transcripts. As a result, the utility company is able to protect the users' sensitive information

at the cost of obtaining less accurate statistical data.

Note that the above methods mainly focus on the centralized PPDA, which cannot be directly applied to the distributed cases. Under distributed PPDA, all participants interact with their neighbors to obtain the aggregated global information, while the privacy of each participant is preserved. The local load perturbation method requires that all local consumers have enough storage devices or controllable loads to hide the load profile. Data anonymization may be too complex to realize the distributed PPDA. CBC technologies may cause much communication and computation cost due to intensive interactions when the network scales up. RNA methods may be applied in the distributed PPDA, but how to define the privacy degree with partial information and how to guarantee the required accuracy with the privacy preservation guarantees are different and interesting problems. Plentiful distributed privacy-preserving schemes have been proposed for typical distributed data aggregation methods, e.g., consensus, distributed optimization, and data selection, which are introduced as follows:

- Privacy-preserving maximum consensus (PPMC) (Duan et al. 2015; Wang et al. 2017): To preserve the initial state of maximum consensus while maintaining the finite time convergence, the PPMC method was proposed in 2015, where all nodes independently generate and transmit random numbers before sending out initial states. Then, under the assumption that an adversary can attain all transmitted states, a differentially private maximum consensus (DPMC) algorithm was developed, where nodes add Laplacian noises to initial states for local interactions.
- Privacy-preserving average consensus (PPAC) (He et al. 2018a, 2016): PPAC is to guarantee average consensus while protecting the initial state of all nodes from being inferred by the internal or external attacker.
 - *Exact PPAC*: An exact average consensus with privacy preservation guarantees was achieved by adding the zero-sum decreasing noise.
 - *Differential PPAC*: To guarantee differential privacy, a typical method is adding random noise to the original data for data release. The basic conditions of differential privacy with the general random noise adding mechanism were investigated.
 - *Secure PPAC*: To mitigate the pollution from dishonest nodes, an enhanced secure consensus-based data aggregation algorithm was proposed that allows neighbors to detect dishonest nodes and guarantees an error bound for the case with undetectable dishonest nodes.
- Privacy-preserving distributed optimization (PPDO) (Nozari et al. 2018): PPDO obscures the private local function by noisy message exchange or local function perturbation, under which multiple agents are still able to cooperatively minimize the sum or average of their local cost functions with/without constraints to some extent.
 - Local message perturbation (LMP): LMP hides the sensitive local cost function by adding noise to the messages which are broadcast to neighbors while having the optimality guarantee, for example, differentially private distributed optimization algorithms.
 - Local function perturbation (LFP): LFP protects the private local cost function by obscuring it, where the objective function is perturbed by noise, while the accuracy of the global optimizer has an analytical bound.
- Privacy-preserving distributed selection (PPDS) (Liu and Chen 2018): PPDS hides the local statistic information of distributed data owner from neighbors or the eavesdropper, e.g., mean and sum, while the required states can still be selected in a distributed way, e.g., the median.
- Distributed privacy-preserving estimation theory (He and Cai 2017; He et al. 2018b): To preserve data privacy, a node may add random noise to its original data for information exchange at each iteration. Nevertheless, an eavesdropping node is able to estimate the

other's original data depended on its received information. It is worth mentioning the following results:

- The estimation accuracy and data privacy are measured in terms of (ϵ, δ) -data privacy, defined as the probability of ϵ -accurate estimate (the difference between an estimation and the original data that is within ϵ is no larger than δ).
- A theoretical framework which achieves the optimal distributed estimation is developed, where the agents optimize the estimation of neighbors' original data using the local information.
- The disclosure probability is derived under the optimal estimation. These theoretical results have been successfully applied in distributed energy management for smart grids (Zhao et al. 2017).

Key Applications

PPDA involves in the data processing for the statistical analysis for huge volumes of measurement data in a geographically distributed or logically distributed network. Typical application scenarios include smart meters data aggregation in smart grids, time synchronization for wireless sensor networks, and efficient resource allocation in end-to-end networks.

Definitions

Privacy-preserving data collection system collects sensitive data from data contributors and detects meaningful general information by gathering data while protecting data contributors' privacy.

Background

Nowadays, with the advance of big data analytics, organizations have become increasingly interested in collecting and analyzing user data. For example, web browsers and mobile apps often collect system logs and usage patterns as a means to guide the development of future versions; crowdsourcing platforms, such as Mechanical Turk, also provide a convenient way to collect information from contributors. However, the collection of user data could incur significant privacy risks, as demonstrated in several past incidences, e.g., (Hansell 2006), where accidental leakage of sensitive data led to public outrage, reputation damage, and legal actions against the data collector. The need of a privacy-preserving way to collect data from users has been recognized by both industry and academia.

Local differential privacy (LDP) is the state-of-the-art approach for *privacy-preserving data collection*, which has been implemented in the Google Chrome browser (Erlingsson et al. 2014). Its main idea is to ensure that the data collector (i) never collects or possesses the exact values of any personal data and yet (ii) would still be able to derive general statistics about the users. In particular, in LDP, each user locally perturbs her data under differential privacy (Dwork 2008), which is a strong and rigorous notion of privacy that provides plausible deniability; then, the user sends the perturbed data to the collector. As such, LDP protects both the users (against privacy risks) and the data collector itself (against damages caused by potential privacy breaches).

A series of works study the problem of frequency estimation following local differential privacy. After Warner's first study on *randomized*

response (Warner 1965), many works have explored a variety of perturbation mechanisms for achieving theoretical optimal utility. In (Kasiviswanathan et al. 2011), the local privacy model is first formalized. To handle the practical issues for private distribution estimation, RAPPOR (Erlingsson et al. 2014) is proposed to generalize Warner's randomizer from binary alphabets to k-ary alphabets.

Foundations

Privacy-preserving data collection system with local differential privacy (LDP) (Kasiviswanathan et al. 2011) is a data collection framework based on ϵ -differential privacy (Dwork 2008). Under this framework, each data contributor (e.g., a user of a website) locally perturbs her own data using a randomized mechanism that satisfies ϵ -differential privacy, before sending the noisy version of her data to a data collector. Specifically, a randomized mechanism M satisfies ϵ -differential privacy, if and only if for any two neighbor databases D and D' (explained shortly) that differ in exactly one record, and any possible output s of M , we have the following inequality:

$$\frac{Pr[M(D) = s]}{Pr[M(D') = s]} \leq e^\epsilon$$

Intuitively, given an output s of mechanism M , an adversary cannot infer with high confidence (controlled by ϵ) whether the input database is D or its neighbor D' , which provides plausible deniability for individuals involved in the sensitive database. Here, ϵ is a system parameter called the privacy budget that controls the strength of privacy protection. A smaller ϵ signifies stronger privacy protection, since the adversary has lower confidence when it tries to distinguish between D and D' .

The concept of differential privacy was originally proposed for the setting where a trusted data curator, who possesses a database containing the exact data records from multiple individuals,

publishes perturbed statistics derived from the database using a randomized mechanism. Hence, the definition of differential privacy involves the notion of “neighbor databases.” In contrast, in LDP, there is no trusted data curator; instead, each individual perturbs her own data record under ε -differential privacy. In this situation, D and D' are two singleton databases, each containing exactly one record. Since two neighbor databases differ by exactly one record, essentially D and D' represent two arbitrary records. In the problem studied in this paper (described in section “[Background](#)”), every record is a set of items, and each of D and D' represents such an item set.

A privacy-preserving data collection solution includes both (i) a user-side data perturbation mechanism and (ii) an algorithm executed by the data collector for computing statistical information from the noisy data received from the users. The former one’s main requirement is to satisfy differential privacy. Theoretically, every differentially private mechanism can be potentially applied to the LDP setting to be run at each user. In reality, however, most mechanisms for enforcing differential privacy are designed to run at a central data curator who has access to the exact records of all users, with the goal of publishing perturbed statistics based on these records. In LDP, neither assumption holds, since the privacy protection algorithm is run by individual users who do not have access to other user’s data, and that the information to be released is the perturbed data, not analysis results. Consequently, although the fundamental mechanisms for differential privacy such as the Laplace mechanism and the geometric mechanism can be applied to LDP, more sophisticated ones, e.g., for the frequent itemset mining, cannot be applied to LDP as they require global knowledge of all users’ data. Further, perturbing the data at the user side is only part of the solution; traditional differentially private mechanisms do not address the other important problem in LDP, i.e., computing statistics at the data collector based on individuals’ noisy data.

To understand the privacy-preserving data collection system with local differential privacy, an example of randomized response mechanism

achieves local differential privacy is shown below. Specifically, randomized response asks each user a sensitive question whose answer can be either yes or no, e.g., “Are you HIV positive?” The goals are (i) that each user answers the question with plausible deniability and (ii) that the data collector can compute an unbiased estimate of the percentage of users whose answer is “yes” (resp. “no”). To do so, each user flips a coin before answering the question. If the coin turns head, the user provides her true answer (let’s say it is “yes”); otherwise, she reports the opposite of her true answer (i.e., “no”). To adapt RR to satisfy LDP, we make the coin biased, with a probability p (resp. $1 - p$) to turn head (resp. tail). It has been proven (e.g., in Erlingsson et al. 2014) that randomized response satisfies ε -differential privacy with the following value of p :

$$p = \frac{e^\varepsilon}{1 + e^\varepsilon}$$

After that, the data collector in randomized response estimates the percentage of users with an “yes” answer. If the data collector simply outputs the percentage of “yes” among the noisy answers (denoted by c), the results would be biased, due to the random perturbations performed at the users. To correct this, the data collector reports the following adjusted estimate:

$$c' = c \times c_\varepsilon, \text{ where } c_\varepsilon = \frac{1}{1 - 2p}$$

Randomized response is limited to the case where each user answers a binary question. Nevertheless, it is still a fundamental building block for even more sophisticated LDP solutions.

Definitions

Private truth discovery in cloud-assisted crowdsensing systems aims to mine trustworthy information from noisy sensory data collected from different mobile users in cloud-empowered crowdsensing applications while enforcing the provision of data privacy.

Historical Background

Crowdsensing is an emerging sensing paradigm which enables cost-effective sensory data collection from ubiquitous mobile devices (Ganti et al. 2011). It has found a wide spectrum of practical applications like health monitoring, indoor floor-plan reconstruction, environmental monitoring, and smart transportation. In the real practice, crowdsensing systems are usually deployed on top of the cloud to collect and process sensory data, due to its well-known advantages like scalability, economical cost, and on-demand services. As the sensory data collected from different mobile users are usually unreliable (possibly due to the variation in sensor quality, ambient noise, skill level, etc.), it is of immense importance to properly aggregate the sensory data so as to obtain trustworthy information. Toward this problem, the technique of truth discovery has been recently proposed, which is able to infer individual users' reliability information directly from the collected sensory data and then infer the truthful information via reliability-aware aggregation (Li et al. 2015).

Despite the usefulness, practically applying truth discovery in cloud-empowered crowdsensing systems faces critical privacy barriers that should be overcome satisfactorily. Firstly, the sensory data collected from the mobile users may reveal sensitive information to the cloud service provider such as health conditions, locations, personal interests, and more (Ganti et al. 2011). More seriously, the cloud service provider might also misuse the collected data for making profit or even suffer from data breaches incidents, which have been shown to be common in practice (Zheng et al. 2017a, c). Secondly,

the reliability degrees of individual users inferred from the sensory data also demand delicate protection, as it may be potentially exploited to infer sensitive information like education level, age, and profession (Miao et al. 2015). Therefore, how to preserve data privacy while maintaining the functionality of truth discovery is a critical challenge that should be carefully tackled in cloud-empowered crowdsensing systems. Toward this problem, a line of research work (Miao et al. 2015; Xu et al. 2017; Miao et al. 2017; Zheng et al. 2017b, 2018; Tang et al. 2018; Cai et al. 2018) has been presented in the literature.

Truth Discovery Framework

The most representative truth discovery framework in the plaintext domain is the CRH framework proposed by Li et al. (2016), which is also the foundation for most of existing privacy-preserving truth discovery designs. The CRH framework for truth discovery in mobile crowdsensing applications is introduced as follows. Let $\mathcal{N} = \{1, 2, \dots, N\}$ denote the set of sensing tasks and $\mathcal{U} = \{1, 2, \dots, M\}$ denote the set of users. Besides, let y_n^i denote the sensing value for the sensing task $n \in \mathcal{N}$ from user $i \in \mathcal{U}$ and w_i denote the reliability degree, i.e., weight, of user i . The CRH truth discovery framework aims to produce the estimated ground truth y_n^* for each sensing task $n \in \mathcal{N}$. There are two iterative procedures to be conducted: (1) weight update and (2) truth update.

- (1) **Weight update.** This procedure is to compute a weight w_i for user $i \in \mathcal{U}$, given that the estimated ground truth y_n^* for each sensing task n is fixed. A user will be assigned a weight with a high value if his/her sensing values are close to the estimated ground truths. The weight w_i for user i is computed as

$$w_i = f \left(\sum_{n=1}^N d(y_n^i, y_n^*) \right), \quad (1)$$

where f is a monotonically decreasing function and $d(\cdot)$ is a distance function measuring the difference between users' sensing values and the estimated ground truths. In more detail, w_i is computed via.

$$w_i = \log_2 \left(\frac{\sum_{i=1}^M \sum_{n=1}^N d(y_n^i, y_n^*)}{\sum_{n=1}^N d(y_n^i, y_n^*)} \right). \quad (2)$$

Meanwhile, the following normalized squared distance function is commonly used as the distance function d .

$$d(y_n^i, y_n^*) = \frac{(y_n^i - y_n^*)^2}{\sigma_n}, \quad (3)$$

where σ_n is the standard deviation of all sensing values for sensing task n .

- (2) **Truth update.** This procedure is to estimate the ground truth y_n^* for each sensing task $n \in \mathcal{N}$, given that each user weight w_i is fixed. Specifically, the estimated ground truth y_n^* for the sensing task n is computed via weighted aggregation of users' sensing values, i.e.,

$$y_n^* \leftarrow \frac{\sum_{i=1}^M w_i y_n^i}{\sum_{i=1}^M w_i}. \quad (4)$$

Advances on Privacy-Preserving Truth Discovery

In the literature, some research efforts have been recently presented to enable privacy-preserving truth discovery for cloud-empowered crowdsensing systems. Here a brief overview of these works is provided.

The initial research efforts were from Miao et al. (2015), where the PPTD framework was presented for enabling privacy-preserving truth discovery in crowdsensing systems. The PPTD framework relies on the threshold Paillier cryptosystem to protect the confidentiality of users' sensory data and weights. In particular, the cloud server in the PPTD framework is responsible for aggregating any encrypted intermediate data values across users, based on the homomorphic

property of the Paillier cryptosystem. And a number of users are required to assist the cloud server in the decryption of any encrypted intermediate aggregate values. Since the PPTD framework heavily relies on the cost-expensive threshold Paillier cryptosystem and requires a number of users for decryption assistance, it does not perform well in performance, incurring considerable computation and communication overhead. Later, some follow-up works (Xu et al. 2017; Zheng et al. 2017b; Miao et al. 2017) were presented, which proposed different security designs so as to achieve better performance than the PPTD framework. The work by Xu et al. (2017) achieved better performance at the price of sharing a secret key among all the users, which can make the system brittle in the face of user compromise. The work by Zheng et al. (2017b) mainly built on a lightweight aggregation protocol which neither requires the sharing of a secret key among users nor needs to rely on an additional party for key setup. The work by Miao et al. (2017) operated under a two-cloud-server model and relied on additively homomorphic encryption for supporting efficient and privacy-preserving truth discovery.

Despite the effectiveness, the designs in all the above works required users to keep staying online for active participation throughout the whole privacy-preserving truth discovery procedure. Considering this requirement may not always be satisfied in practice, Tang et al. (2018) proposed a design enabling noninteractive privacy-preserving truth discovery, where users do not need to stay online to actively participate in the truth discovery procedure after they submit the (encrypted) sensory data. Their design was built under a two-server model and mainly relied on the classical secure two-party computation technique called garbled circuits to realize privacy-preserving truth discovery on the cloud side. And several optimization techniques were presented to customize their design to achieve good efficiency.

In addition to the above works which proposed designs tailored for static data, there are also some other works that focused on different application contexts. For example, Zheng et al. (2018)

targeted crowdsensing applications with long-tail data, where the number of sensing tasks performed by different users may vary significantly. They proposed a design to support encrypted confidence-aware truth discovery as to achieve high accuracy in estimating the ground truth for long-tail data. Cai et al. (2018) targeted crowdsensing applications with data streams, where sensory data are collected in a streaming fashion. Namely, the new data continue to sequentially arrive over time. They proposed a design to support privacy-preserving streaming truth discovery, in which data are scanned only once and no iterative computation over the same data records is required.

Key Applications

Private truth discovery in cloud-empowered crowdsensing systems can be beneficial to mine truthful information in a privacy-preserving manner from applications, where different mobile users report conflicting measurements about the same sensing objects, such as traffic conditions, broken public utilities, gas prices, weather conditions, and air quality.

[Behavioral economics](#); [Expected utility theory](#); [Prospect theory](#)

Definitions

Prospect theory (PT) is a Nobel-prize winning behavioral economic theory proposed by Daniel Kahneman and Amos Tversky. It explains the decisions among alternatives under uncertainty by taking into account the human psychology. It generalizes the expected utility theory (EUT), which fails to explain a collection of observations involving risky choices.

Historical Background

In a wireless network, an agent (e.g., a mobile user) often needs to face *uncertainty* when allocating the resources. Externally, in the shared wireless spectrum, he may encounter channel fluctuations (e.g., fading and shadowing) and interference from other agents, when he chooses the power level to transmit or the wireless channel to access, respectively. Internally, he may encounter uncertainty of his future data demand, which affects his choice of data plan and the consumption of his data quota.

Traditionally, the *expected utility theory* (EUT) is widely adopted in the literature for wireless resource allocation. In EUT, an agent aims to maximize the weighted average of his utilities under different uncertain outcomes. Mathematically, with uncertainty, there are I possible outcomes, where α_i is the i th outcome and p_i is the corresponding probability that it occurs. Let y be the decision variable on the resource allocation and $\mathcal{Y}$ be its feasible set. Let $f(y, \alpha_i)$ be the *utility* of the decision-maker when his decision is y and the realized outcome is α_i . For example, in wireless communications, $f(y, \alpha_i)$ may represent the agent's throughput when the transmit power is y and the channel condition is α_i . Under EUT, the decision-maker maximizes his expected utility by solving

$$\max_{y \in \mathcal{Y}} \sum_{i=1}^I f(y, \alpha_i) p_i. \quad (1)$$

While the EUT aims to optimize the agent's expected performance, it may not be able to accurately capture the realistic decision-making if the agent is a *human being*, who is influenced by his cognitive limitations and risk preferences. First, a human decision-maker may not always be a *fully rational* agent, who maximizes his expected utility. Instead, he is often *bounded rational* and cannot maximize his expected utility due to his cognitive limitations. Moreover, it was reported in Kahneman and Tversky (1979) that humans are often *risk-averse* when gaining utility but *risk-seeking* when losing utility, where this evaluation is relative to a neutral reference point.

As a result, Daniel Kahneman and Amos Tversky proposed the *prospect theory* (PT) (Kahneman and Tversky 1979) that generalizes EUT to explain these additional observations. Later on, in 2002, Daniel Kahneman was awarded the Nobel Prize in economics "for having integrated insights from psychological research into economic science, especially concerning human judgment and decision-making under uncertainty." It has then been widely applied in many areas, which includes finance (Jin and Zhou 2008), consumption decisions (Koszegi

and Rabin 2009), industrial organizations (Paul and Koszegi 2012), labor supplies (Camerer and Loewenstein 2004), and political sciences (Levy 2003).

However, the study of resource allocation in communication networks based on PT only emerged recently. In this article, the mathematical formulation of PT, its key applications in communication networks, and some open research problems will be discussed.

Prospect Theory

In this section, the three key features in the mathematical modeling of PT, namely, reference point, s-shaped value function, and probability distortion (Kahneman and Tversky 1979, 2000), are discussed in details. The cognitive features behind them are highlighted.

Reference Point

The EUT assumes that an agent's level of satisfaction is characterized by the expected utility that he achieves. In other words, if two agents receive the same expected utility, they should be equally happy. However, as humans, our level of satisfaction is also related to the outcome that we expect (Kahneman 2011): an outcome above our expectation is a gain that makes us happy, while an outcome below our expectation is a loss that disappoints us.

Let R_p be the *reference point*, which indicates the agent's expectation of the outcome. The agent considers an outcome a *gain* if it is higher than the reference point and a *loss* if it is lower than the reference point. Thus, having a higher reference point means that the agent is more likely to treat an outcome as a loss, while having a lower reference point means that he is more likely to treat an outcome as a gain.

S-Shaped Asymmetrical Value Function

Besides the impact of the reference point, there are two other important cognitive features at the heart of PT, namely, diminishing sensitivity and loss aversion (Kahneman 2011).

Diminishing sensitivity reflects a fundamental feature of human cognition, where the marginal change in the perception diminishes with respect to the distance from the reference point. For example, regarding the sensory perception, a small increment of light intensity in a dark room is more detectable than that in an illuminated room. Regarding the change of wealth, the difference between a gain of \$200 and a gain of \$300 appears to be larger than that between a gain of \$2200 and a gain of \$2300. Similarly, the difference between a loss of \$200 and a loss of \$300 appears to be larger than that between a loss of \$2200 and a loss of \$2300 (Kahneman and Tversky 1979). In other words, a decision-maker often experiences a diminishing marginal utility when evaluating a gain and a diminishing marginal disutility when evaluating a loss.

Loss aversion refers to the human's stronger preference of avoiding losses than achieving gains. This asymmetry between the power of positive and negative experiences has an evolutionary history, where organisms that treat threats as more urgent than opportunities have a better chance to survive (Kahneman 2011).

Putting it together, due to the diminishing sensitivity, the *value function* $v(x)$, which maps an objective outcome x to the agent's subjective valuation, is concave in the gain region (i.e., when $x \geq 0$) and convex in the loss region (i.e., when $x < 0$) under a zero reference point. Moreover, due to loss aversion, it is asymmetrical around the reference point, where the function is steeper for losses than for gains (i.e., $|v(-x)| > v(x)$ for any $x > 0$). The result is an s-shaped asymmetrical value function $v(x)$ as illustrated in Fig. 1a. A commonly used value function in the PT literature in the form of Tversky and Kahneman (1992) and Kahneman and Tversky (2000)

$$v(x) = \begin{cases} x^\beta, & \text{if } x \geq 0, \\ -\lambda(-x)^\gamma, & \text{if } x < 0, \end{cases} \quad (2)$$

is shown, where $\lambda \geq 1$, $0 < \beta \leq 1$, and $0 < \gamma \leq 1$. Notice that all the outcomes are measured relative to the reference point R_p , which is normalized to $R_p = 0$ in the figure. The

parameter λ is the loss penalty parameter, where a larger λ indicates that the agent is more afraid of a loss. The parameters β and γ are the risk parameters, where the value function of the gain part is more concave (i.e., the decision-maker is more risk-averse) when β approaches zero, and the value function of the loss part is more convex (i.e., the decision-maker is more risk-seeking) when γ approaches zero. It should be noted that EUT is a special case when $\lambda = 1$ and $\gamma = \beta = 1$, where the value function becomes a linear function of $v(x) = x$.

As a result, combining the impact of both the reference point and the s-shaped value function, an agent is more likely to encounter losses under a high reference point R_p and is thus more risk-seeking. On the other hand, under a low reference point R_p , the agent is more likely to encounter gains and is thus more risk-averse.

Probability Distortion

It was shown that the decision weight people assign to an outcome is not identical to the probability of that outcome. For example, consider the following four events of a 5% improvement in winning a big prize: (a) from 0% to 5%, (b) from 5% to 10%, (c) from 60% to 65%, and (d) from 95% to 100%. It was shown that events (a) or (d) are more significant than events (b) or (c) (Kahneman 2011).

First, the larger impact of event (a) is due to the *possibility effect*, which causes low probability events to be weighted more than their objective probability. It can be used to explain the gambling behavior, where people are willing to buy lottery tickets for a very low probability of winning a big prize. Second, the large impact of event (d) is due to the *certainty effect*, which causes events that are almost certain (e.g., 95% chance of winning a prize) to be weighted less than their objective probability. To sum up, human tends to *overweight low probability events* but *underweight high probability events*.

Figure 1b illustrates the probability distortion function $w(p)$, which captures humans' psychological overweighting of low probability events and underweighting of high probability events (Kahneman and Tversky 1979). A commonly

Prospect Theory for Communication Networks, Fig. 1 (a) The s-shaped asymmetrical value function $v(x)$ with reference point $R_p = 0$. (b) The probability distortion function $w(p)$

used probability distortion function is Prelec and Loewenstein (1991)

$$w(p) = \exp(-(-\ln p)^\mu), \quad 0 < \mu \leq 1, \quad (3)$$

where p is the *objective* probability of an outcome and $w(p)$ is the corresponding *subjective* probability. Here, μ is the probability distortion parameter, which reveals how a person's subjective evaluation distorts the objective probability. A *smaller* μ means a *larger* distortion. When $\mu = 1$, it refers to the case of EUT without probability distortion that $w(p) = p$.

Optimization Problem

Combining the three features in PT, the decision-maker aims to solve

$$\max_{y \in \mathcal{Y}} \sum_{i=1}^I v(f(y, \alpha_i) - R_p) w(p_i), \quad (4)$$

which is a *non-convex* optimization problem in general due to the s-shaped value function $v(x)$. In reality, an operator's decision is influenced by not only the consideration of the expected utility maximization but also by the level of his *risk preference*, and they are both captured in problem (4). As a result, problem (4) is more general than problem (1).

Key Applications

In this section, the literature that applied prospect theory to the resource allocation problems involving uncertainties in communication networks and smart grids is reviewed as follows:

- *Wireless random access*: The first paper of this subject is due to Li and Mandayam (2012), who compared the equilibrium strategies of a two-user random access game under EUT and PT. A linear value function was considered. They extended the analysis in Li and Mandayam (2014) to a general random access channel model with more users.
- *Spectrum investment in cognitive radio networks*: Yu et al. (2016) considered the spectrum investment of a virtual operator in sensing and leasing. Although sensing is usually cheaper than leasing, the amount of available spectrum obtained by sensing is *uncertain* due to the primary users' activities in the licensed band. The authors showed that compared to an EUT operator, both the risk-averse and risk-seeking operator achieve a smaller expected profit. On the other hand, a risk-averse operator can guarantee a larger minimum possible profit, while a risk-seeking operator can achieve a larger maximum possible profit.

- *Mobile data trading*: Yu et al. (2017) considered a mobile data trading market, where users can trade their monthly 4G mobile data quota with each other. In this market, a user needs to make the trading decision under the *uncertainty* of his future data usage in the remaining time of the billing cycle. By comparing with the EUT benchmark, the authors showed that a PT user with a lower reference point is more risk-averse and is thus more willing to buy mobile data to reduce the risk that his future data demand will exceed the quota. Moreover, when the probability of having a high future data demand is low, a PT user is more willing to buy mobile data due to the probability distortion comparing with an EUT user.
- *Pricing*: Yang et al. (2015) considered the impact of end-user decision-making on wireless resource pricing, where there is an uncertainty in the quality of service (QoS) guarantees. They designed the data pricing and channel allocation algorithms based on PT.
- *Smart grid*: Wang et al. (2014) formulated a noncooperative game among consumers in an energy exchange system. They applied PT to explicitly account for the users' subjective perceptions of their expected utilities. Xiao et al. (2015) studied the static energy exchange game among microgrids that are connected to a backup power plant. They analyzed the Nash equilibria under various scenarios based on PT and evaluated the impact of user's objective weight on the equilibrium of the game.

Open Problems

In this section, some open problems for the applications of PT to communication networks are outlined.

- *Shifting reference point*: The literature mentioned above mainly considered the *static* user decision in one time slot. It is interesting to consider the *dynamic* decisions in multiple

time slots, where a user's reference point may change over time.

- *Risk preference estimation*: In order to solve problem (4), it is important to know the agent's risk preference accurately. Yu et al. (2017) proposed an algorithm to estimate the parameters in the value function. Nevertheless, further studies are needed to accurately estimate the reference point and probability distortion function as well.

Protocol Stack Architecture for Wireless Sensor Networks

Definition

Wireless sensor network:

Wireless sensor network (WSN) refers to a group of spatially dispersed and dedicated sensors for monitoring and recording the physical conditions of the environment and organizing the collected data at a central location. WSNs measure environmental conditions like temperature, sound, pollution levels, humidity, wind, and so on.

OSI model:

The Open Systems Interconnection model (OSI model) is a conceptual model that characterizes and standardizes the communication functions of a telecommunication or computing system without regard to its underlying internal structure and technology. Its goal is the interoperability of diverse communication systems with standard protocols. The model partitions a communication system into abstraction layers.

The original version of the model defined seven layers.

Protocol stack:

The protocol stack or network stack is an implementation of a computer networking protocol suite or protocol family. The terms are often used interchangeably; strictly speaking, the suite is the definition of the Communications protocols, and the stack is the software implementation of them.

Historical Background

WSNs are designed for gathering information in a large geographical area. Massive sensors are networked together as a wireless sensor network to strengthen the power of sensing. Such typically self-configuring network is often controlled through a software core engine. To demonstrate the important engine structure of WSNs, protocol stack architecture is present.

ISO, The International Organization for Standardization, promotes worldwide standards for commercial, industrial, and proprietary, acting as an international standard-setting body. A standard is an agreed or required level of quality or attainment. ISM (The Industrial, Scientific and Medical) radio bands established by ITU (the International Telecommunications Union) finds its applications into microwave ovens, medical diathermy machines, radio-frequency process heating, etc. Taking both the low power consumption of WSNs and the ISM frequency bands into consideration, WSN standards from ISO have developed the functions and protocols to interface with other wired or wireless networks.

The IEEE 802.15 working group has many different approved standards (represented by 802.15.x) related to WSNs. Currently, all 802.15.x approved standards have proposed only physical (PHY) and medium access control (MAC) layers, leaving the design of network, transport, and application layers for other parties.

At present, WSN standards (Hossam 2016) include: ANT, EnOcean, IEEE 802.15.4 Low Rate WPANs, IEEE 802.15.3, Impulse

Radio Ultra-Wide Bandwidth Technology 802.15.4a, INSTEON, ISA100.11a, MyriaNed, Wibree(BLE), Wavenis, WirelessHART, ZigBee, Z-Wave, 6LoWPAN, etc.

Key Applications

WSNs have many key applications, which can be categorized into daily life, environmental, health, industrial, military, multimedia, and surveillance. Specifically speaking, WSNs can be used for biological or chemical detection, health care monitoring, public security, system control, target tracking, traffic control, etc.

As WSNs have spanned a wide range of important applications, it is necessary to satisfy the diverse requirements of applications by considering some design goals. These goals are application-specific design, adaptive network operation, data fusion and localized processing, fault tolerance and reliability, low-cost and small sensor nodes, resource-efficient design, scalable architectures and efficient protocols, self-configuration and self-organization, secure design, and time synchronization.

Differences with Other Networks

Similar to a general wireless network, a WSN also transmits a packet with a header among sensor nodes. But the existing algorithms designed for general wireless networks, such as ad hoc networks, cannot be directly applied for WSNs (Ian et al. 2006; Jennifer et al. 2008), which is due to some reasons:

1. Broadcast transmission is used due to restricted memory space and limited power supply, compared with point-to-point communication in general wireless networks.
2. Sensor nodes are with both the larger numbers and the higher probability of permanent failure, compared with a typical ad-hoc network.

Protocol Stack Architecture

WSN protocol stack design is based on the OSI seven-layer model. This model is designed by the International Organization for Standardization (ISO) and consists of physical layer, data link layer, network layer, transport layer, session layer, presentation layer, and application layer.

Since too many layers of OSI model can bring WSNs overlay complex and implement difficulty, WSNs cannot take all the design requirement of the OSI model. Therefore, the WSN protocol stack has adopted only five layers. The protocol stack architecture of WSNs (Shuang-Hua 2014) in Fig. 1 consists of the physical layer, data link layer, network layer, transport layer, and application layer, backed by a power management plane, mobility management plane, task management plane, quality-of-service (QoS) management plane, and security management plane.

The WSN protocol stack consists of five layers. Each layer has a specific set of task and works independently.

The responsibility of the first layer, namely, the physical layer, includes

1. Defining the cable-compatible connector for sensor nodes.
2. Managing the connections among sensor nodes and their communication transmission medium.
3. Managing carrier frequency, data encryption, frequency selection, robust modulation, signal detection, signal transmission, and break reception.

The responsibility of the second layer, namely, the data link layer, includes

1. Providing services such as error detection and correction, MAC, reliable delivery.
2. Enabling massive nodes successfully accessing and fully sharing communication transmission medium.
3. Minimizing packet collision with neighboring sensors.

**Protocol Stack
Architecture for Wireless
Sensor Networks, Fig. 1**
Protocol stack architecture
of WSN

The responsibility of the third layer, namely, the network layer, includes

- 1. Establishing communication transmission paths between sensor nodes and routing packets along the established paths successfully.
- 2. Designing routing protocols with different requirements for diverse paths setup policy, such as the best QoS paths, the best lifetime paths.

The responsibility of the fourth layer, namely, the transport layer, includes

- 1. Providing with transparent and reliable communications between end sensors, i.e., the transmitter and receiver.
- 2. Considering transport layer protocol forms, such as the transmission control protocol (TCP) and the user datagram protocol (UDP).
- 3. Providing a reliable communication service with connection-oriented transport layer protocols, such as TCP, for the aim of extensive error handling, flow control, transmission control.
- 4. Providing an unreliable communication service with connectionless transport layer protocols, such as UDP.

The responsibility of the fifth layer, namely, the application layer, includes

- 1. Designing applications including, File Transfer Protocol (FTP), Hypertext Transfer Protocol (HTTP), Simple Network Management Protocol (SNMP), Secure Shell (SSH), and Telnet.
- 2. Dealing with sensed information, data encryption, data formatting, and storage.
- 3. Scanning and detecting the availability of network resources for the underlying layers.

The WSN protocol stack is backed by five management function planes for the integration of the administration, configuration, maintenance, and operation.

The responsibility of the power management plane includes

- 1. Monitoring the sensor node’s current power level and the amount of power consumption.
- 2. Turning off functionality to preserve energy when the power level is below some threshold.

The responsibility of the mobility management plane includes

- 1. Handling WSN layout issues.
- 2. Managing sensor node location and network activity distribution.
- 3. Detecting movement of nodes to maintain node to node communication and data route.

The responsibility of the task management plane includes

1. Assigning sensing tasks to necessary nodes in the sensing field.
2. Scheduling sensor nodes without sensing tasks for the optimization of data routing and aggregation.

The responsibility of the QoS management plane includes

1. Managing data latency, data acquisition accuracy, fault tolerance, system performance.
2. Determining QoS metrics to deal with performance optimization, error control, and fault tolerance.

The responsibility of the security management plane includes

1. Handling functionalities such as authentication, encryption, threat detection and recovery, intrusion detection.
2. Controlling sensor nodes to access sensitive data.

[Binding](#); [IP mobility](#); [Local mobility anchor](#); [Mobile access gateway](#); [Mobile node](#); [Mobility session](#); [Proxy mobile IPv6](#)

Background

IP mobility protocols are designed to allow mobile nodes to remain reachable while moving around in the Internet. There are two types of

mobility management approaches: client-based and network-based.

Client-Based Mobility Management – The mobile node is required to be involved in the mobility management. Exchange of IP mobility signaling messages between the mobile node and a mobility anchor in the network enables the creation and maintenance of a binding between the mobile node's home address and its care-of address. It essentially allows the mobility anchor node to tunnel the traffic bound to the mobile node's home address to its care-of address. IP mobility support for IPv6 hosts is specified in Mobile IPv6 specification [RFC-3775].

Network-Based Mobility Management – There is another approach to solving the IP mobility problem and is the network-based approach. This mobility management approach does not require the mobile node to be involved in the exchange of signaling messages between itself and a mobility anchor located in the network. A proxy mobility agent in the network tracks the mobile node's movements and performs the signaling with the mobility anchor on behalf of the mobile node. This essentially removes the requirement of client involvement in mobility management. Proxy Mobile IPv6 (PMIPv6) is a network-based mobility management protocol standardized by IETF. The base protocol is specified in RFC 5213 and RFC 5844; other protocol extensions to Proxy Mobile IPv6 are specified in additional RFC specifications.

Protocol Overview

Proxy Mobile IPv6 is a protocol for building a common and access-technology agnostic mobility core. The key capability of Proxy Mobile IPv6 is its ability to provide mobility management support to a mobile node without requiring its participation in any IP mobility-related signaling. The mobility entities in the network will track the mobile node's movements and will initiate the mobility signaling and set up the required routing state in the network.

The core functional entities in the Proxy Mobile IPv6 domain are the local mobility anchor (LMA) and the mobile access gateway (MAG).

The local mobility anchor is responsible for maintaining the mobile node's reachability state and it is the topological anchor point for the mobile node's home network. All the mobile node's inbound and outbound IP traffic is always routed through the local mobility anchor.

The mobile access gateway is the entity that performs the mobility management on behalf of the mobile node, and it resides on the access link where the mobile node is anchored. The mobile access gateway is responsible for detecting the mobile node's movements to and from the access link and for initiating binding registrations to the mobile node's local mobility anchor.

The following diagram is a representation of a mobility management domain based on Proxy Mobile IPv6 (Fig. 1).

Proxy Mobile IPv6 is a control-plane-driven protocol, which uses the control-plane signaling to establish dynamic tunnels between the MAG and LMA. The mobility entities use control plane for session management and for user-plane management. Mobility messages such as PBU/PBA, BRI/BRA, HB, UPN/UPA are used for triggering the protocol peers for activating various functions on the mobile node's binding state. The user plane is based on standard layer-3 encapsulation and routing mechanisms and is used for forwarding the mobile node's IP packets. The supported tunnel encapsulation types are IP-GRE, IP-in-IP, and IP-UDP. The encapsulation mode for the tunnel is negotiated as part of the Proxy Mobile IPv6 signaling messages.

The MAG tracks the mobile node's movements (Attach/Detach triggers) on the access link based on ARP, DHCP, IPv6 Neighbor Discovery, and link-layer specific protocols (e.g., NAS signaling in LTE). Furthermore, the mobile node obtains the IP address configuration from the MAG using DHCP and/or IPv6 Neighbor Discovery.

Proxy Mobile IPv6 protocol is used for network-based mobility management in various

Proxy Mobile IPv6, Fig. 1
Proxy Mobile IPv6 domain

Proxy Mobile IPv6, Fig. 2
Mobility chaining

mobile architectures including 3GPP, 3GPP2, and WiMAX. The protocol is specified over various network interfaces in their system architectures. The protocol is also used for supporting various IP mobility use-cases in enterprise, transportation, and other vertical markets. Applications such as mobile networks, mobile local loops, Wi-Fi Traffic Offload, Connected Car management, and Community Wi-Fi networks are some of the examples where this protocol is deployed.

Mobility Chaining

Mobility domains based on Proxy Mobile IPv6 can be chained in a hierarchical fashion. Chaining allows localization of the mobility events. The mobile node’s session is anchored on the top-level LMA and also on the local LMA in the access network. The mobile node’s movements

within the access network are hidden from the top-level LMA. The user-plane traffic for the mobile node is always routed through the LMA in the top level.

Mobility domain chaining can be achieved by enabling LMA and MAG functions on the same node with some interworking between the two functions for session correlation. Chaining is typically suited for large scale mobility deployments connecting mobility domains based on various access technologies under a common mobility core (Fig. 2).

PMIPv6 Protocol Operation

When a mobile node enters a Proxy Mobile IPv6 domain and attaches to an access link, the mobile access gateway on that access link, after identi-

fyng the mobile node and acquiring its identity, will determine if the mobile node is authorized for the network-based mobility management service.

If the network determines that the mobile node is authorized for network-based mobility service, the network will ensure that the mobile node using any of the address configuration mechanisms permitted by the network will be able to obtain the address configuration on the connected interface and move anywhere in that Proxy Mobile IPv6 domain. The obtained address configuration includes the address(es) from its home network prefix(es), the default-router address on the link, and other related configuration parameters. From the perspective of each mobile node, the entire Proxy Mobile IPv6 domain appears as a single link, the network ensures that the mobile node does not detect any change with respect to its layer-3 attachment even after changing its point of attachment in the network.

The mobile node may be an IPv4-only node, IPv6-only node, or a dual-stack (IPv4/v6) node. Based on the policy profile information that indicates the type of address or prefixes to be assigned for the mobile node in the network, the mobile node will be able to obtain an IPv4, IPv6, or dual IPv4/IPv6 address and move anywhere in that Proxy Mobile IPv6 domain.

Example Call Flow

The following is an example call flow for a mobile node's attachment to a Proxy Mobile IPv6 network (Fig. 3).

Signaling Plane

The operation of Proxy Mobile IPv6 protocol is primarily based on the protocol signaling between the mobile access gateway and the local mobility anchor. The base protocol specified in RFC 5213, RFC 5844, and other specifications defines the structure and semantics of the interface between the mobile access gateway and the local mobility anchor. Although the protocol does not define any signaling interface

between the mobile node and the mobile access gateway, it is an essential interface needed for the protocol operation. The mobile access gateway relies on standard IP interfaces (e.g., DHCP, IPv6 ND, ARP) and access-technologic specific layer-2 interfaces for learning the mobile node's Attach/Detach events, for learning the mobile node's authenticated identity and for delivering IPv4/IPv6 address configuration to the mobile node.

Protocols Used Between MN to MAG

Protocols	Description	Reference
Layer-2	Link-layer protocols are used for learning the mobile node's attach/detach events on the access link, for learning the mobile node's authenticated identity and for obtaining the mobile node's policy profile	Refer to access specific interfaces (e.g., WLAN/3GPP specifications)
ARP	Used for detecting the mobile node's presence on the access link	RFC-826
IPv6 ND	Used for delivering the IPv6 address configuration	RFC-4861RFC-4862
DHCP	Used for delivering the IPv4/IPv6 address configuration	RFC-2131RFC-3315

Signaling Messages Between MAG and LMA

Protocol messages	Description	Reference
PBU/PBA	Messages for session management	RFC-5213
BRI/BRA	Messages for binding revocation management	RFC-5846
UPN/UPA	Messages for notifications related to session state	RFC-7077
Heartbeat	Messages for peer state detection	RFC-5847

Proxy Mobile IPv6, Fig. 3 Call flow for PMIPv6 signaling

Proxy Mobile IPv6, Fig. 4
Packet forwarding path

User Plane

See Fig. 4

Traffic from CN to MN

The mobile node's inbound IP traffic from the correspondent node is always routed through

the local mobility anchor. The IP address that is assigned on the mobile node is topologically anchored on the LMA and so the local mobility anchor is always in the path for the mobile node's traffic.

When a correspondent node sends a packet to the mobile node's home address, the packet

Proxy Mobile IPv6, Fig. 5 IPv4 control-plane stack

hits the local mobility anchor as it advertises the reachability for that prefix associated with that IP address.

The local mobility anchor on receiving the packet will forward the packet through a bidirectional tunnel to the mobile access gateway and which in turn will deliver it to the mobile node on the access link. There will be a prefix route for the mobile node through the bidirectional tunnel.

Traffic from MN to CN

The mobile node’s outbound IP traffic is always tunneled from the mobile access gateway to the local mobility anchor.

When a mobile node sends a packet to a correspondent node, the packet is first received by the first-hop router and which is the mobile access gateway. The mobile access gateway tunnels the packet to the mobile node’s local mobility anchor.

The local mobility anchor on receiving the packet from the tunnel removes the tunnel header and forwards the packet to the correspondent node.

Protocol Stacks

Control-Plane Traffic

The following are the supported control-plane protocol stacks on LMA and MAG.

When using IPv6 transport, the following protocol stack gets activated on the MAG and on the LMA. The Mobility Header is an extension header in the IPv6 packet. However, when IPsec is used between MAG and LMA for securing the

Proxy Mobile IPv6, Fig. 6 IPv6 control-plane stack

Proxy Mobile IPv6, Fig. 7 IPv6 user-plane protocol stack

messages, IPsec ESP header is added right above the IPv6 header (Fig. 5).

When using IPv4 transport, the following protocol stack gets activated on the MAG and the LMA. However, when IPsec is used between MAG and LMA for securing the messages, IPsec ESP header is added right above the IPv4 header and below the UDP header (Fig. 6).

User-Plane Traffic

The following are the supported user-plane protocol stacks on the MAG and the LMA.

When using IP-in-IP encapsulation, the IP packet from the mobile node is encapsulated in an IPv6 packet. However, when IPsec is used between MAG and LMA for securing the user-plane traffic, IPsec ESP header is added right above the IPv6 header (Fig. 7).

When using GRE encapsulation, the IP packet from the mobile node is encapsulated in a GRE packet. GRE is supported both on IPv4 and IPv6 transports. However, when IPsec is used between MAG and LMA for securing the user-plane traffic, IPsec ESP header is added right above the IPv4 header and below the GRE header (Fig. 8).

Applications

Hybrid Access Support

Cable operators are exploring options to offer higher throughput access to the Internet. This is especially true with the incumbent xDSL service providers with a large deployment of both xDSL and LTE networks. These operators have no immediate opportunity for the expensive FTTH network upgrade or upgrade to cable Internet, but they have to compete with the cable operators who are able to offer much higher throughputs with their DOCSIS 3.x-based access architectures. Customers on legacy networks

have issues viewing high-definition videos. To address this requirement, operators are using Proxy Mobile IPv6 technology with multipath extensions for LTE and DSL link aggregation.

In this deployment, the MAG functionality is collocated on the CPE, and the LMA functionality is collocated on a network node such as BNG.

The approach allows the operator to specify SLA (Latency, Jitter, Loss) on an application basis and with path preferences (LTE preferred, otherwise DSL). The forwarding functions in the anchor and the CPE will constantly measure the path preferences and ensure the application flows are routed on the paths that meet the application SLA (Fig. 9).

Proxy Mobile IPv6, Fig. 8 IPv4 user-plane protocol stack

Mobile Local Loop

Mobile operators are offering enterprise private routing services over 3G/4G infrastructure. This service allows an enterprise to securely link all their remote small branch offices over a mobile network, without the need for dedicated leased lines, or IPsec/SSL-based VPN's which come with all the provisioning complexity. By leveraging the wireless spectrum, mobile operators are

Proxy Mobile IPv6, Fig. 9

Hybrid access support with Proxy Mobile IPv6

Proxy Mobile IPv6, Fig. 10 Mobile local loop support with Proxy Mobile IPv6

Proxy Mobile IPv6, Fig. 11 WLAN-EPC interworking based on 3GPP S2a Interface

able to offer this private routing service over a 3G/4G network and are able to eliminate any costs associated with the last mile circuit such as payments to local carriers with dedicated leased lines. CPE devices equipped with 3G/4G wireless modules are being used for IP connectivity at the branch office. This new concept is referred to as “Mobile Local Loop.”

Proxy Mobile IPv6 is the key protocol used for enabling this use-case. The MAG function resides in the CPE device and the LMA function with the business logic is enabled on the router in the service provider network (Fig. 10).

WLAN-EPC Interworking

Mobile operators are expanding their network coverage by integrating various access technology domains (e.g., wireless LAN, CDMA, and Long-Term Evolution (LTE)) into a common IP mobility core.

The idea is to provide a consistent set of services and IP mobility support to a mobile node irrespective of the access technology used for the IP connectivity.

For supporting this interworking, the 3GPP has defined interface points allowing integration of Trusted WLAN network with mobile packet core. The 3GPP S2a Proxy Mobile IPv6 [TS23402] reference point, specified by the

3GPP system architecture, defines the protocol interworking for building such integrated multiaccess networks. In this scenario, the mobile node’s IP traffic is always tunneled back from the mobile access gateway in the access network to the local mobility anchor in the home network (Fig. 11).

Terminology

Term	Description
AAA	Authentication, Authorization and Accounting
AP	Access Point
BCE	Binding Cache Entry
BRA	Binding Revocation Acknowledgement
BRI	Binding Revocation Indication
BULE	Binding Update List Entry
GRE	Generic Routing Encapsulation
IP-in-IP	IP Packet Encapsulation in IP Header
LMA	Local Mobility Anchor
MAG	Mobile Access Gateway
MN	Mobile Node
CN	Correspondent Node
NAI	Network Access Identifier
PMIPv6	Proxy Mobile IPv6
RA	Router Advertisement
RS	Router Solicitation

[QoE metrics](#); [QoE models](#)

Definition

As defined in ITU-T (2008) by the Telecommunication Standardization Sector of International Telecommunication Union (ITU-T), quality of experience (QoE) is “the overall acceptability of an application or service, as perceived subjectively by the end-user.” According to Brunnström et al. (2013) by Qualinet, QoE is defined as “the degree of delight or annoyance of the user of an application or service. It results from the

fulfillment of his or her expectations with respect to the utility and/or enjoyment of the application or service in the light of the user’s personality and current state.” Correspondingly, QoE assessment models assimilate various network-related performance metrics and application-specific quality metrics to gauge user’s satisfaction toward an application or service.

Historical Background

With the fast development of wireless networks in recent years, multimedia services have become one of the most popular and dominant applications on mobile devices. In particular, mobile video traffic is expected to increase by ninefolds between 2016 and 2021, accounting for over 78% of global data traffic in mobile networks by 2021 (Cisco 2017). Due to the attributes of wireless networks, the quality of multimedia delivery cannot be as good or stable as in a wired network. Traditionally, objective quality of service (QoS) metrics, such as bit error probability (BEP), packet delay, and packet loss, are often used to evaluate multimedia quality. However, QoS is insufficient to gauge user-perceived service quality.

To assess users’ overall satisfaction and acceptance of services, quality of experience (QoE) becomes a stronger indicator than the traditional QoS. As defined in ITU-T (2008) by ITU-T, QoE is “the overall acceptability of an appli-

cation or service, as perceived subjectively by the end-user.” QoE incorporates a wide variety of factors from different layers. Thereby, QoE provides a more comprehensive assessment of user-perceived quality.

Foundations

Based on the classification in Wang et al. (2017), QoE assessment can be categorized into subjective assessment, objective assessment, and hybrid assessment.

Subjective assessment of QoE relies on human users’ direct input on their evaluation for the perceived service quality. Subjective assessment poses strict requirements on experiment design and participant selection. The assessment procedure can be costly and even impractical in some cases. Objective assessment of QoE uses mathematical models to derive the value of QoE from some objectively measurable factors as input variables. The objective assessment methods are more viable although the obtained QoE value is only approximate and not verified by real measurement. Hybrid assessment attempts to employ subjective assessment in a lab environment to calibrate the objective QoE model so that more accurate objective assessment is applied in a larger scale.

Considering the dominance of video traffic in current networks, we take video services as an example to introduce different QoE assessment methods. Traditional IP-based video streaming is usually based on real-time transport protocol (RTP), which runs on top of the user datagram protocol (UDP). The real-time streaming protocol (RTSP) and session description protocol (SDP) are often used together with RTP for session setup and control. Due to issues with firewall and network address translation (NAT) traversals, most videos nowadays are delivered using the hypertext transfer protocol (HTTP) running over the transport control protocol (TCP). The video delivery over HTTP is actually simple bulk download of a video file to the end user’s device. The user experience with progressive downloading is similar to streaming, since a media player

is capable of beginning playback as the media file is being downloaded from an HTTP Web server. This fast-start playback relies on metadata located in the header of the media file (instead of the end of the media file in old formats) to retrieve the downloaded content in the local buffer.

Dynamic adaptive streaming over HTTP (DASH) (Stockhammer 2011) is a popular video delivery technique for conventional HTTP Web servers. DASH segments a media file into chunks of short intervals at multiple playback rates (encoding bit rates). Based on the media presentation description (MPD) file, which describes segment information (timing, URL, media characteristics such as video resolution and bit rates), a video client selects a bit rate to enable a fast session start-up and adaptively switches the bit rate of the next segment to request based on network conditions, device capabilities, user preferences, and so on. The bit rate adaptation is a key component to maintain high-quality video delivery with minimum stalls or rebuffering events during the playback.

To gauge user-perceived service quality, mean opinion score (MOS) is a widely used subjective QoE metric, which is usually expressed in a 5-point scale, where 5 equals *Excellent*, 4 equals *Good*, 3 equals *Fair*, 2 equals *Poor*, and 1 equals *Bad*. Subjective QoE depends on both picture distortions of video coding and transmission impairments. In Seshadrinathan et al. (2010), Seshadrinathan et al. used a four-parameter monotonic logistic function to fit objective video quality assessment (VQA) metrics to subjective difference mean opinion score (DMOS). A variety of VQA metrics that focus on the low-level video characteristics are evaluated, e.g., peak signal-to-noise ratio (PSNR), structural similarity (SSIM), video quality metric (VQM), and motion-based video integrity evaluation (MOVIE) index. Simpler video parameters are considered in the acceptability QoE model proposed in Song and Tjondronegoro (2014) for mobile video, such as quantization parameter, logarithm bit rate, frame rate, and content type. Instead of using the 5 or 11 scales of MOS, the acceptability QoE model adopts binary measures

that access general acceptability and pleasant acceptability of users for mobile video.

There are also QoE models that further incorporate network-related parameters. For instance, in Li et al. (2014), Li et al. carried out experiments with 30 participants to assess user-perceived QoE for video and audio clips delivered over the IEEE 802.11 wireless network in a lab environment. The subjective QoE quantified in a 5-point MOS scale is related to three objective metrics, including bit error probability, packet loss rate, and packet delay. It is found that the subjective QoE is sensitive to audio/video content although consistent with objective QoS metrics. Statistical difference-of-means tests show that the video with slower motion and fewer colors is likely to offer better delay tolerance.

Different from subjective assessment that directly involves tests with human users, a QoE model in objective assessment often uses a mathematical model to link MOS with objective QoE factors at different layers (Rengaraju et al. 2012; Reichl et al. 2013). This becomes a more viable approach to estimate the user-perceived QoE. Key performance indicators (KPIs) at the network level (e.g., throughput, packet loss, delay, and jitter) can capture quality at the network level (i.e., QoS), whereas quality at the application level is related to key quality indicators (KQIs), (e.g., start-up delay, freezing interruptions, and picture distortions for video streaming) (Rengaraju et al. 2012).

In G.1070 recommendation (ITU-T 2007) of ITU-T, the QoE model for video-telephony applications accounts for network parameters such as one-way end-to-end delay and packet loss, as well as video codec parameters, e.g., spatial resolution, frame rate, and encoding bit rate. In Khan et al. (2010), the heuristic MOS prediction model takes into account a network-level parameter, packet error rate, in addition to application-level parameters such as video bit rate and frame rate.

The logarithm scaling law in service quality perception is discussed in Reichl et al. (2013) from the perspectives of microeconomics and psychophysics. The authors also clearly distin-

guish between the quality degradation parameters like packet loss rate and resource-based stimulus parameters like transmission bandwidth and encoding bit rate. Unfortunately, the logarithm laws are only justified in the proposed QoE models for Web browsing and file download in the universal mobile telecommunications system (UMTS) with high-speed packet access (HSPA). The additive log-logistic model for networked video proposed in Zhang et al. (2013) can capture the relationship of visual quality against impairment-related features caused by both compression and transmission. In particular, the freezing duration due to packet loss is referred as one candidate metric, while a higher prediction accuracy can be achieved with more additional features.

Next, we introduce an example QoE model to give the readers a more concrete understanding. In Dobrian et al. (2011), Dorian et al. propose a number of video quality metrics based on user perception, including join time, buffering ratio, rate of buffering events, average bit rate, and rendering quality. The QoE model defined in De Vriendt et al. (2013) for adaptive video services involves average segment quality level and standard deviation of segment quality level. The QoE model proposed in Mok et al. (2011) further incorporates the impact of video freezes by taking into account the duration and frequency of video freezes. A comprehensive QoE model in Claeys et al. (2014) combines the two models in De Vriendt et al. (2013) and Mok et al. (2011). It incorporates *the average quality level, the standard deviation of the quality level, and the duration and frequency of video freezes* and quantifies MOS by

$$MOS = \max(5.67 \cdot \mu - 6.72 \cdot \sigma - 4.95 \cdot \phi + 0.17, 0)$$

where

$$\mu = \frac{\sum_{k=1}^K \frac{Q_k}{N}}{K}, \quad \sigma = \sqrt{\frac{\sum_{k=1}^K \left(\frac{Q_k}{N} - \mu \right)^2}{K - 1}}$$

$$\phi = \frac{7 \cdot \max\left(\frac{\ln F_{freq}}{6} + 1, 0\right) + \frac{\min(F_{avg}, 15)}{15}}{8}.$$

Here, N denotes the total number of quality levels and K denotes the total number of segments in the video. Moreover, Q_k is the quality level requested for the k th segment, F_{freq} is the ratio of the number of video freezes to the number of segments, and F_{avg} is the average duration of all freezes. As seen, the QoE captures quality metrics in various aspects and provides a holistic assessment of user-perceived quality.

Key Applications

QoE assessment models are fundamental in network resource management for multimedia service provisioning in order to enhance user experience.

We still take video services as an example to introduce a key application of QoE models. It is known that wireless networks are highly varying due to channel fading and user mobility. To counter against the high dynamics and deliver high-quality video, adaptive bit rate streaming (ABS) is an effective technique for HTTP-based video delivery. ABS intends to provide users with the best available video quality in corresponding network condition by adopting bit rate adaptation schemes. Traditionally, many bit rate adaptation schemes (Akhshabi et al. 2011; Thang et al. 2012; Miller et al. 2012; Liu et al. 2011) aim at the improvement of video QoS such as throughput, packet loss, starvation probability, freezing duration and rate, etc. Here, freezing and starvation mean that the playback buffer at the end user runs below the smallest video decoding block such that the playback is interrupted.

With an appropriate QoE model, ABS can target at QoE improvement, i.e., the improvement of overall user-perceived quality. A QoE model can capture the effects of a variety of objective metrics on user perception. When the QoE model is used to guide the bit rate adaptation, the holistic perception of QoE rather than some isolated QoS metrics can be improved. For example, in Bentalab et al. (2016), the authors consider a QoE model that utilizes the most influential metrics on end-user satisfaction including start-up delay, the number of stalls, average video quality, and the number of video quality switches. Accordingly,

the optimal bit rate for the next segment to be downloaded is determined dynamically to maximize the QoE of each video client.

Definition

MOS	Mean opinion score
PSNR	Peak signal to noise ratio
QoE	Quality of experience
QoS	Quality of services
SSIM	Structural similarity

History Background

Past few years have witnessed the booms of Internet video. The online video service providers, such as YouTube, Amazon, Hulu from USA and Youku, Tencent, Toutiao from China are becoming the main players in the market of video entertainment (CNNIC 2017; Hossfeld et al. 2011). Mobile phones, over-the-top (OTT) devices, and online streaming are substituting televisions as the new favorable ways for the generation born after 1980. It is necessary for the providers to assess the service quality.

Quality assessment is firstly proposed for digital television, to evaluate the quality of video coding and transmission. Many metrics have been proposed (Seufert et al. 2015), such as the peak signal-to-noise ratio (PSNR), the structural similarity (SSIM), and the subjective metric of the mean opinion score (MOS). The video quality is measured by comparing the original videos with the compressed video, or human subjects are asked to rate the quality.

Quality of service (QoS) is defined by ITU (ITU 2012) to measure the performance of network, not the actual experience of user. The common QoS metrics are throughput, packet losses, delay, jitter, etc.

Online video streaming is an end-to-end video delivery and playback. Its quality depends on video coding and on network conditions as well. Mostly, its quality is assessed by quality of experience (QoE), a user-centric metric that measures the performance subjectively perceived by the user.

The impact factors on QoE are classified into three categories:

1. Video level: video quality (PSNR), frame rate, and resolution

2. Application level: start-up delay, bit rate, stall/rebuffering, and rate oscillation
3. Context level: screen size, browser/player, and screen distance

Key Applications
